Abstract—Quantum Chromodynamics (QCD) is the theory of strong nuclear force, responsible of the interactions between sub-nuclear particles. QCD simulations are typically performed through the lattice gauge theory approach, which provides a discrete analytical formalism called LQCD (Lattice Quantum Chromodynamics). LQCD simulations usually involve generating and then processing data on petabyte scale which demands multiple teraflop-years on supercomputers. Large parts of both, generation and analysis, can be reduced to the inversion of an extremely large matrix, the so-called Wilson-Dirac operator. For this purpose, and because this matrix is always sparse and structured, iterative methods are definitely considered. Therefore, the procedure of the application of this operator, resulting in a vector-matrix product, appears as a critical computation kernel that should be optimized as much as possible. Evaluating the Wilson-Dirac operator involves symmetric stencil calculations where each node has 8 neighbors. Such configuration is really hindering when it comes to memory accesses and data exchanges among processors. For current and future generation of supercomputers the hierarchical memory structure make it next to impossible for a physicist to write an efficient code. Addressing these issues in order to harvest an acceptable amount of computing cycles for the real need, which means reaching a good level of efficiency, is the main concern of this paper. We present here a Domain Specific Language and corresponding toolkit, called QIRAL, which is a complete solution from symbolic notation to simulation code.

I. INTRODUCTION

In a context of fast moving parallel architectures, the design of an optimized LQCD simulation, and in particular of an efficient inversion function is complex. This requires to design, select and combine iterative methods and preconditioners adapted to the problem and the target architecture, to optimize data layout and organize parallelism between nodes, cores, accelerators and SIMD units. In order to harness all resources of the hardware, orchestrating the work on many cores and accelerators, using different levels of parallelism, complex memory hierarchies and interconnect networks takes a large part of the tuning time, often at the expense of the exploration of new algorithms/preconditioners. Indeed, testing new methods can only be achieved with large enough data sets, requiring efficient parallel codes. Several codes and libraries have been designed for Lattice QCD (tmLQCD [10] as part of the European Twisted Mass Collaboration or Chroma [9] as part of the USQCD effort to name a few) and many works have been proposed on code optimization for Lattice QCD, among them recent works on Blue Gene/Q [7], Intel Xeon Phi [12] or clusters of GPUs [11]. While taking architectural features into account is crucial for high performance simulations, the key to exascale simulations also lies in new algorithms, new data layouts and communication patterns. However, designing new iterative methods, combining existing ones, changing data layout within these frameworks and tools is difficult and requires a significant code rewriting effort. This clearly hinders the adaptation of code to new parallel machines, limiting performance and the expected scientific results.

This paper proposes a domain-specific language (DSL), QIRAL, for the description of Lattice QCD simulations, and its compiler to generate parallel code. A domain-specific language can help to separate the high level aspects of the simulation from machine-dependent issues. The contribution of QIRAL is to address this twofold challenge:

- Propose to physicists a domain-specific language expressive enough to enable the description of different models and algorithms, and more importantly, expressive enough to enable algorithmic exploration by composing different algorithms and preconditioners as well as the design of new algorithms.

- Generate from this description efficient codes for parallel machines. Explicit parallelism and data layout are automatically generated and can be guided by the user. The code generated by QIRAL targets shared memory parallel machines, corresponding to one node of larger Lattice QCD simulations. This code uses OpenMP and a library for efficient SIMD operations.

With a higher level description of the Lattice QCD formulation, it becomes easier to try new algorithmic ideas, the high level code is easier to maintain and develop, and therefore makes numerical simulation accessible to a large number of users, not necessarily high performance computing experts. We show
on several architectures, from Nehalem-EX with 128 cores to the Xeon Phi accelerator that the code generated with QIRAL competes in terms of parallel efficiency and performance with tmLQCD, while QIRAL provides an easier framework for the writing of algorithms and the adaptation to new architectures.

This paper is organized as follows: first we describe the DSL in Section II, describe the high-level compiler in Section III. Then the optimizations for locality, parallelism and SIMDization are presented in Section IV. Comparisons with related works are in Section V and experimental results, comparing with tmLQCD and describing strong scalability are shown in Section VI.

The whole project, under the name PetaQCD [1], was partly funded by a grant from ANR, through the program COSINUS-2008, from 2009 up to 2011.

II. THE QIRAL DOMAIN-SPECIFIC LANGUAGE

As one of the purposes of the QIRAL DSL is to give scientists a familiar tool to describe the problem in scope, it makes sense to take an existing system of symbolic notation as the basic language. There are two such systems in most disciplines, LATEX and Mathematica. While we are not attached to a particular one, we chose to use LATEX-like syntax where certain additional macros have been defined. Therefore the QIRAL description can be processed either using the QIRAL compiler to produce program source code or alternatively, by the LATEXtypesetters to produce its documentation, as shown in Figure 1. This means we revive the principle of literate programming coined by Donald Knuth [13]. For instance, the algorithm in Figure 4 is a QIRAL program included into this document as processed by LATEX. The description of the language given in the following complements a description previously presented by the author’s [4].

![Diagram of QIRAL compiler](image)

**Fig. 1.** QIRAL compiler.

QIRAL is an array language for linear algebra, dedicated to the manipulation of sparse matrices defined through tensor products and direct sums of dense matrices as they appear in Lattice QCD. The language relies on specificities of Lattice QCD: the inversion computation is a stencil computation, on a regular, 4D Cartesian mesh (the lattice). The Dirac operator, used for this inversion, is a sparse but regularly structured matrix that can be seen as a diagonal of dense matrices. This operator transforms values from the lattice into new values. These values are made of 12 complex values, indexed by their spin (4 indices) and color (3 indices). Hence for a $24^4 \times 48$ lattice, the Dirac operator is a matrix of $(24^4 \times 48^2 \times 12)^2$ complex values. As it is sparse, its structure carries the parallelism of the computation, hence the language and the compiler captures this structure through the operators building the matrix.

Elements of the language are declarations, equations, algorithms and the goal. Declarations declare symbols and functions with their type. Basic types are boolean, integers, real (R), complex (C) vectors (V), matrices (M), indices and index sets. Vectors and matrices are defined over index sets either defined through the notation $V_1[i,s]$, where $i$ is the possibly multi-dimensional index set for vector $V_1$, or deduced through type inference. A particular element of a vector is accessed by a particular index $d_i$. Figure 2 shows the declaration of the constants used for Lattice QCD, and the definition of Dirac operator as a matrix. The two other matrices, $P_e$ and $P_o$ are projections, keeping only black or white elements of the lattice, like a 4D checkerboard.

**Constant:**

- $\text{Dirac}, P_e, P_o, \gamma_5 \in \text{M}$,
- $L, S, C, \text{even} \in \text{Indexset}$,
- $\gamma \in \text{Index} \rightarrow \text{M}$,
- $U \in \text{Index} \rightarrow \text{M}$,
- $\kappa, \mu, \in \text{R}$,
- $D \in \text{Indexset}$

**Variable:** $s \in \text{Index}, d \in \text{Index}$

$$\text{Dirac} = \text{I}_{L \otimes C} \in \text{S}$$
$$= 2 * i * \kappa * \mu * \text{I}_{L \otimes C} \otimes \gamma_5$$
$$+ -\kappa * \sum_{d \in D} ((J_d I_C) * (U[s \otimes d]) \otimes (I_S - \gamma[d]))$$
$$+ -\kappa * \sum_{d \in D} ((J_d I_C) * (U[s \otimes \gamma M]) \otimes (I_S + \gamma[d]))$$

$$P_e = P_{\text{even}, L} \otimes \text{I}_C \in \text{S}$$
$$P_o = P_{\text{even}, L} \otimes \text{I}_C \in \text{S}$$

**Fig. 2.** Definitions of the Dirac matrix on a Lattice $L$ in QIRAL, and the two projections for even and odd elements ($P_e$ and $P_o$ respectively) of this lattice.

Equations are used to define variables or functions. Figure 3 describes nearly all properties and definitions on the constant and functions used for the simulation. For instance, the function “invertible” is defined for only some expressions.

Algorithms are given as possible definitions for statements or expressions. For instance, the conjugate gradient algorithm in Figure 4 provides the code that compute expressions of the form $x = A^{-1} * b$, when $A$ and $b$ are given. It outputs the value of $x$, i.e. solve the linear system $Ax = b$. 

![Diagram of QIRAL compiler](image)

**Fig. 1.** QIRAL compiler.
Constant:

\[ dx, dy, dz, dt \in \text{Index} \]

\[ D = \{ dx, dy, dz, dt \} \]

isPeriodic(L) = true

\[ U[s \otimes d]^t = U[(s + d) \otimes -d] \]

\[ U[s \otimes d] = U[(s + d) \otimes d] \]

Preconditioner1(\text{Dirac}) = P e

Preconditioner2(\text{Dirac}) = P o

\[ \gamma[d]^t = \gamma[d] \]

\[ \text{diagonal}(\gamma_0) = \text{true} \]

\[ \gamma_0 \ast \gamma[d] = d \]

\[ \text{invertible}(I s + c \ast \gamma_0) = \text{true} \]

\[ \text{invertible}(I s - c \ast \gamma_0) = \text{true} \]

\[ \text{invertible}(-c \ast I s + i \ast \gamma_0) = \text{true} \]

\[ \gamma_0^t = \gamma_0 \]

\[ \text{type}(\gamma[d]) = S \times S \]

\[ \text{type}(U[s \otimes d]) = C \times C \]

\[ \text{type}(\gamma_0) = S \times S \]

\[ \text{vol}(S) = 4 \]

\[ \text{vol}(C) = 3 \]

Fig. 3. Identities of constants used for Lattice QCD.

| Input | \( A \in M, b \in V \) |
| Output | \( x \in V \) |
| Constant | \( \varepsilon \in \mathbb{R} \) |
| Match | \( x = A^{-1} \ast b \) |
| Var | \( r, p, Ap, z \in V, \alpha, \beta, n_r, n_z, n_{z1} \in \mathbb{R} \)
| | \( r = b \) |
| | \( z = A^t \ast r \) |
| | \( p = z \) |
| | \( x = 0 \) |
| | \( n_z = (z \mid z) \) |
| | \( n_r = (r \mid r) \) |
| while \((n_r > \varepsilon)\) do |
| \( Ap = A \ast p \) |
| \( \alpha = n_z/(Ap \mid Ap) \) |
| \( x = x + \alpha \ast p \) |
| \( r = r - \alpha \ast Ap \) |
| \( z = A^t \ast r \) |
| \( n_{z1} = (z \mid z) \) |
| \( \beta = n_{z1}/(n_z) \) |
| \( p = z + \beta \ast p \) |
| \( n_z = n_{z1} \) |
| \( n_r = (r \mid r) \) |

Fig. 4. Conjugate Gradient, normal residual method (CGNR).

The initial statement, in the Match clause, is then defined (and replaced) by the pseudo-code. The Var keyword declares the type of local variables. This algorithm is written using the “algorithm2e” package in \LaTeX, and is not specific to Lattice QCD. The user has the possibility to write new algorithms for Lattice QCD or any other algorithm found in common literature. The QIRAL compiler finds automatically how to compute for instance \( A \ast p \) when \( A \) is instantiated with the Dirac operator.

Most often the validity of a program depends on prerequisites, special properties the inputs must have. These prerequisites are declared in a clause \textbf{Require} and is proved by the QIRAL compiler. The following example illustrates this prerequisite mechanism. Figure 5 describes the Schur complement method that is used as a preconditioner for the conjugate gradient. The condition invertible\((P_e \ast A \ast P_e^t)\) is proved automatically by the compiler when \( A \) matches the matrix \text{Dirac}. To prove this, the property defined previously for the function “invertible” is used. If the compiler is not able to prove the requirements attached to an algorithm, the algorithm is not applied and an error is generated. Notice that on this preconditioning, the statements involve computation of inverse matrices. For the expression \( D_{11}^{-1} \), the QIRAL compiler can prove automatically that \( D_{11} \) is diagonal (when \( A \) is the Dirac operator), and knows how to invert this matrix. For the computation of the expression \((D_{22} - D_{21} \ast D_{11}^{-1} \ast D_{12})\), an iterative method has to be applied.

The goal defines the initial code and the list of algorithms to apply. The algorithms are composed from right to left.

| Input | \( bb \in V \) |
| Output | \( xx \in V \) |
| Templates: | \text{CGNR schur} |
| \( xx[L \otimes C \otimes S] = \text{Dirac}^{-1} \ast bb[L \otimes C \otimes S] \) |

For this goal here the preconditioner \text{schur} is applied on the initial statement, and then the CGNR algorithm. It is possible to chain multiple algorithms, used to apply preconditions before the solvers. The index set \( L \otimes C \otimes S \) represents the Cartesian product of these sets and the domain for the vector \( bb \). At this level, there is no implicit data layout for vectors and matrices. The vector \( bb \) could be either a 4D array of structures, one dimension for each dimension of \( L \) and the structure representing elements indexed by \( C \) and \( S \), or a 1D array of structures, or just a large 1D array of complex values. This is orthogonal to the expression of the algorithm.

The output of QIRAL compiler is a function in C and OpenMP pragmas representing the computation described in the goal, and taking as parameters \( bb \) and \( xx \). All other constant
values (in particular constant matrices) are assumed to be
global.

III. IMPLEMENTATION DETAILS

The QIRAL compiler is based on a rewriting system, Maude [6]. The different steps of this transformation are explained in this section.

A. Algorithms composition and expression simplification

Algorithms are translated into rules of the rewriting system, while equations define the equational theory for the rewriting system. The first step consists in transforming $\text{L}^{\text{Xinput}}$ into a Maude program. Additional modules, defining usual algebraic simplifications are added to this code.

The first step parses the $\text{L}^{\text{Xinput}}$ and captures only what is described in predefined environments, for algorithms, definitions and the goal. Syntactic verification as well as type checking is performed. The output generated is a Maude module, with equations corresponding to definitions, rules corresponding to algorithms, and an unique Maude statement, corresponding to the goal.

The algorithms declared in the goal are applied, in turn, to the statements provided. These statements are terms for Maude. The Match clause is the left-hand side (lhs) of the rule, while the pseudo-code corresponds to a term that is the right-hand side (rhs) of the rule. Any statement matching the lhs will then be rewritten in the rhs. In order to identify this match, Maude unifies the input variables of the lhs with the real values, corresponding to the binding of the formal parameters of the actual function parameters of a function call. If a Require clause exists, it constitutes the condition for the rewriting. The first statement is provided by the goal, then algorithms are applied successively.

Definitions and properties are considered by Maude as defining the equational theory for the rewriting system. Actually, these equations are handled as automatic rewriting rules: Maude automatically applies all possible equations, rewriting their lhs into rhs, until the term is normalized. For instance, the property $x \times (y + z) = x \times y + x \times z$, stating the distributivity of $+$ over $\times$, will only be used to distribute the operators, not to factorize terms.

The main objective of this formal rewriting is to eliminate all terms that are equal to zero. In Lattice QCD, the Dirac matrix used in the problem is sparse, but built from dense matrices with a regular structure. To obtain such simplifications, an additional module defines properties for the linear algebra operators, on complex, vectors and matrices: Addition is commutative and associative, multiplication is associative and distributes over the addition, binary subtraction is converted to unary minus, transposition distributes over the addition and multiplication, etc. Moreover, some properties are also defined for permutation and projection matrices, in particular to handle Schur preconditioning.

B. Generating Element-wise Computation

The term obtained after the first application and simplification step still manipulates matrices and vectors representing the whole lattice. Parallel loops are generated to iterate over the lattice component of the index sets used by all vectors. The different phases of the QIRAL compilation are driven by meta-rewriting rules. The user here can change the parameters for the compiler and choose for instance 4D iterators of the domain (building one loop for each dimension of $L$), 1D iterator (linearized space) or any combination, performing tiling for instance. For this, the user has to indicate in the properties that the lattice is decomposed into sub-lattices:

\[ L = L_1 \otimes L_2 \]

where $L_1$ and $L_2$ are two index sets. $L_2$ represents then sub-lattices and $L_1$ is the iteration domain, iterating through these different blocks.

The generation of loops for Lattice QCD is straightforward, as all array statements are parallel. All such loops are therefore parallel, possibly nested. Parallelism is expressed through OpenMP.

C. Open Issues

A number of difficulties may arise during this high level compilation step, since the range of properties and algorithms that can be described is not limited.

- Convergence: the properties the user define have to form a convergent rewriting system. For instance if the properties $x \times (y + z) = x \times y + x \times z$ and $x \times y + x \times z = x \times (y + z)$ are simultaneously present, the compiler is unable to know which one to apply (no priority). Maude is not able to detect such situation. For algorithms, preconditions, there is no such issue since the user defines the sequence of algorithms to apply.

- Confluence: this only concerns properties and definitions. Confluence means that any order of application of the properties leads to the same resulting term. Some recent works [2], [8] have shown that this can be checked automatically. The impact is that depending on the order of the properties given by the user, there is a risk the code generated is not the same. This has not occurred in QIRAL so far.

These two limitations are therefore more theoretical than practical. More work though has to be done in order to provide a high quality development environment to users, in particular for the identification of the reasons why an algorithm cannot be applied to a particular code (the requirements are not fulfilled).

IV. CODE OPTIMIZATIONS

Once parallel loops are generated, several code optimizations are applied. These transformations are also described in the rewriting system, with built-in modules of QIRAL, in a similar way to a compiler such as Stratego [20]. Current optimizations range from loop transformations, versioning and data layout. The output of this phase is a C-code with OpenMP.

A. Improving Locality

Loops fusion is a transformation to reduce reuse distances, hence improving locality. To check if fusion is valid, a simple dependence analysis, based on dependence distance,
is computed. The fusion method is applied on consecutive
independent loops that share the same iterators, and is applied
on all code until no more fusion is possible. This simple
strategy is sufficient for Lattice QCD generated codes.

Following this fusion, the regions of arrays that are writ-
ten/read by all loops, and the regions that are inputs/outputs
of loops are computed. All arrays that are used only in one
loop are scalar promoted. The resulting values are allocated on
the stack, and aligned for further vectorization. This reduces
memory consumption.

Both transformations are applied automatically.

B. Versioning Matrix Multiplication

The computation involve many multiplications of vectors
by constant matrices, accounting for transformations on spin
and color (5 and C index sets respectively). These matrices
are small, of size 3 × 3 and 4 × 4 respectively, and the
latest have only 2 non-null elements per line, these elements
being among {1, −1, i, −i}. Therefore specialization of these
product is necessary in order to obtained better performance.
These matrix-vector multiplications appear in expressions of
the form (M1 ⊗ M2) · V with M1 and M2 the two matrices
multiplied by a tensor product, and V is a 12 element vector.

In this case the QIRAL compiler uses the identity

\[(M1 \otimes M2) \ast V = M1 \ast V \ast M2^T\]

where on the lhs, V is considered a matrix of size 3 × 4
and \(\ast\) stands for the matrix product. Therefore, instead of
using general matrix multiplication, QIRAL compiler finds
these occurrences and calls versioned matrix multiplications.
Specializing such multiplications for these particular sizes,
in particular performing SIMDization, is essential for perfor-
ance. These functions correspond to the hot-spot of the codes
generated by QIRAL. The codes of these functions are hand-
written in libqiral library as presented in Figure 1.

Other expressions can be replaced by library calls, and
QIRAL changes expressions on vectors and matrices into
BLAS calls (or specialized BLAS). The fact that the QIRAL
compiler automatically identifies these functions in the code
generated from the different algorithms facilitates the opti-
mization process and is an asset of QIRAL. The optimization
of these functions in libqiral, specializations of BLAS,
can indeed be achieved by an expert in high-performance
computing, independent of any Lattice QCD context.

C. Optimizing Data layout and Iterators

The choice of data layout is essential for performance. The
dimensionality of the data structures (how many dimensions
to the array) and the temporal locality loosely depend on the way
the index domains are iterated. In QIRAL, loop iterators and
number of loops are selected according to the transformation
on data layout to achieve. Three different transformations are
explored by the QIRAL compiler.

Tiling is a well established approach to reduce the overhead
impact of memory accesses or inter-node communications. In
our code generation framework, tiling can be specified by
decomposing the lattice into sub-lattices and iterating in each
sub-lattice in turn. As the Lattice QCD computation is an 8
point stencil (2 neighbors in each of the 4 dimensions), tiling
leads to spacial reuse of each element read by the stencil,
provided the tile fits into the cache. Note that as all loops
are initially parallel, by tiling we create innermost sequential
loops, and keep the outermost loops parallel. When using
an accelerator, tiling is essential for effective and optimal
data transfer [18]. An important point here is that for given
a tile, we may need to pack the necessary data to proceed
with. This is required for instance when we need to distribute
the tiles among several processors or threads, or to offload
tiled calculations into accelerator units. Another technical
aspect, which sounds non-trivial, is the organization of the
computation related to the border of the tiles. In most of the
cases, data communications occur only between the borders.
Consequently, the computation of a tile has to be split into two
parts, one for the bulk and another for the border. We should
be able to generate code accordingly in future work.

Even-odd preconditioning (or Schur complement method)
leads to computation on only one element out of 2 in the
lattice. These elements are accessed as the white squares of
a 4D checkerboard. The QIRAL compiler analyzes the set of
elements accessed for each array, and arrays are allocated only
for the elements accessed. The loop domains are also redefined
accordingly, thus no conditionals are created. Half-lattice ar-
rays are therefore created when even-odd preconditioning is
applied. This avoids useless memory strides, improving spacial
locality, and reduces the in-memory working-set.

Finally, as the lattice is a 4D lattice, 2 options are possible:
either vectors are indexed with a 4D index (meaning there
are four loops), or their indices are linearized. As the 4D
space is a torus, the computation of the index for all the
neighbors requires a modulo arithmetic operation. This is
simpler with a 4D index than with a 1D linearized index. Both
versions can be generated, and combined with tiling or even-
odd transformations.

Figure 6 shows an example of the code automatically
generated by the QIRAL compiler. Note that all statements
are calls to functions. The QIRAL compiler has matched
expressions with these functions, all corresponding to BLAS
functions or specialized BLAS. These functions are imple-
mented in the libqiral library.

D. Hand-tuned Optimizations

As presented in the previous section, the QIRAL compiler
generates code for Lattice QCD that calls dedicated versions of
BLAS functions. This versioning is due to constant and simple
matrices, special sizes or coefficients. Different versions for
these functions are implemented: one corresponds to a naïve
C implementation, letting the compiler perform optimizations.
This has the advantage of simplifying the port to new archi-
tectures. Other versions are obtained by SIMDization of these
functions, either through the Intel SPMD Program Compiler
(ISPC) [16], or through manually-written code using compiler
intrinsics.

The compiler ISPC requires adding a few extra keywords to
standard C in order to help SIMDization. Back-ends for ISPC
are Intel architectures with SSE, AVX, AVX-2 and in future
versions, Xeon Phi SIMD. For complex value manipulation,
ISPC tries to generate SIMD code with real and imaginary
#pragma omp parallel for
for(iL = 0 ; iL < L / 2 ; iL += 1)
{
    double complex tmp[12] __attribute__((aligned(0x1000))) ;
    double complex IDschur9[12] __attribute__((aligned(0x1000))) ;
    double complex IDschur10[12] __attribute__((aligned(0x1000))) ;
    xgemmGAMMAPidx(& IDschur5[12 * layouteven(sup(idxodd(iL),dy, L))],tmp);
    xgemmGAMMAPidy(& IDschur5[12 * layouteven(sup(idxodd(iL),dx, L))],tmp);
    xgemmGAMMAPidz(& IDschur5[12 * layouteven(sup(idxodd(iL),dz, L))],tmp);
    xgemmGAMMAPidt(& IDschur5[12 * layouteven(sup(idxodd(iL),dt, L))],tmp);
    xcopy(12, IDschur9, IDschur10) ;
    xscal(IDschur9, kappa); // use of intrinsics.
}

Fig. 6. Excerpt of the code generated by the QIRAL compiler for the CGNR algorithm with the Schur preconditioning.

parts in different vectors. For complex values allocated contiguously, this requires the use of strided loads and stores (named GATHER and SCATTER in Intel ISA), not available on Sandybridge for instance.

Alternatively, complex values can be loaded into the same vectors, storing imaginary and real parts contiguously. Depending on the instruction set, complex multiplication is then implemented either using a shuffle operation, or directly dedicated SIMD instructions. Use of shuffle operations or of these instructions requires on the architectures considered the use of intrinsics.

Besides SIMDization, for shared-memory non-uniform (NUMA) architectures, memory allocation has to take into consideration the precise cores that are using this memory. The use of NUMA policy library is a way to distribute memory among the cores, according to their predefined affinity. This hand-optimization is conducted on all structures allocated before the execution of the function generated by QIRAL.

V. RELATED WORKS

Since it is a heavily CPU time consuming type of application, LQCD was the focus of many developments and papers in the last 15 years. To name a few, some recent works target mostly Intel processors like Chroma [9] on Xeon Phi [12], for a Wilson-Dirac Lagrangian type, or mostly the BlueGene family like tmLQCD [10] on the BlueGene/Q supercomputer [7] with the twisted-mass Lagrangian type. A whole bunch of works also appeared in the last years targeting the GPUs, [11], [5], and the latter are definitely part of our own road map: QIRAL will have a great impact on the GPU coding due to the flexibility it provides, specifically for data-layout.

The Spiral language [17] was obviously the precursor of the QIRAL tool and the model for this work on a LQCD-dedicated DSL, specifically designed for sparse matrices with very small conditioning factor. Qiral initial work was described in [4]. It is a multi-disciplinary project [1] merging fruitfully Lattice QCD theory labs like LPT/CNRS, High Energy Physics people like LAL/IN2P3/CNRS and HPC Parallel Computing experts coming from several INRIA teams (Orsay, Bordeaux) and CAPS-Entreprise. Pochoir [19] is also a similar tool targeting at stencils.

But while Spiral model was inspiring to QIRAL, the former is only targeting at Signal Line Processing, where the latter is fully managing the algorithm, together with the data layout issues, and this part is crucial to improve computing speed. This new tool will allow theory physicists to propose, validate and evaluate the efficiency of their new algorithms more easily and quickly. It will speedup as well the inversion coding for new types of Lagrangian [14] (Clover [3], Overlap [15], and so on).

To summarize, even if the current version is this running on a single node with threads (no MPI), the very huge effort achieved for the data-layout will allow for an easier mixed implementation (MPI-like, OpenMP), and the performances in terms of CPU speed for the global algorithm is very attractive, even for rather large QCD lattices (up to $2^{23}$-node lattice already tested). This is very important, since there was always a huge gap between small and large lattices when comparing their behavior, because this application is both memory-size and memory-bandwidth bound.

VI. PERFORMANCE RESULTS

The following architectures are used for the experiments:

<table>
<thead>
<tr>
<th>Name</th>
<th>Processor</th>
<th># of cores (hyperthreading)</th>
<th>Clock in Ghz</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nehalem-EX</td>
<td>Intel X7560</td>
<td>4 × 32 (2)</td>
<td>2.26</td>
</tr>
<tr>
<td>SandyBridge1</td>
<td>E5-2680</td>
<td>16 (2)</td>
<td>2.7</td>
</tr>
<tr>
<td>SandyBridge2</td>
<td>E5-2687W</td>
<td>16 (2)</td>
<td>3.1</td>
</tr>
<tr>
<td>Haswell</td>
<td>i5-4670T</td>
<td>4 (1)</td>
<td>2.3</td>
</tr>
<tr>
<td>Xeon Phi</td>
<td>SE10P</td>
<td>60 (4)</td>
<td>1.1</td>
</tr>
</tbody>
</table>

The Nehalem-EX and the Sandybridge1 correspond to Curie machines from the TGCC Supercomputer center, Curie Fat and Curie Thin respectively. The same compiler, ICC, is used for the compilation of tmLQCD and QIRAL generated codes.

Several iterative methods are written with QIRAL. Figure 7 presents some of these methods, for two architectures: CGNR,

CRNE, MCR1 and MCR2 with some preconditioners: Schur and preMCR. We observe that while MCR2 exhibits the best work still relies on the compiler: register allocation, generation of FMAs, scheduling. The code generated by QIRAL has been quickly ported to these architectures, and then code tuning has focused on the library used by QIRAL (with versioned BLAS), using intrinsics and aggressive in-lining.

Figure 8 presents timing results on different architectures, comparing tmLQCD code with QIRAL generated code. For QIRAL, the “hand-optimized library” corresponds to the best version obtained, using intrinsics (AVX, AVX2, Xeon Phi) for Sandybridge, Haswell and Xeon Phi architectures. The Nehalem EX version does not use SSE SIMD intrinsics. This explains why QIRAL/Nehalem EX version is more than two times slower than tmLQCD. For Xeon Phi, the performance displayed corresponds to the use of all the 60 cores, and a linear speed-up can be observed by using an increasing number of cores. The ISPC compiler has been used to generate SIMD version of matrix multiplication of size $3 \times 4$ on complexes. The ISPC compiler is still in development, does not fully work for Xeon Phi. Figure 8 shows that the level of performance reached with ISPC is not competing with the level for hand-tuned intrinsics.

The strong scalability of the code generated by QIRAL is evaluated on Xeon Phi and Nehalem-EX architectures. Figure 9 shows efficiency results for different number of cores. The same method, a conjugate gradient with Schur preconditioning is used in all cases, with a lattice of size $24^3 \times 48$ and an error of $10^{-14}$.
on different architectures, in particular their SIMDization. Besides, the fine tuning of the library functions used by QIRAL would enable to run Lattice QCD simulations on a larger scale.

A hand-tuned Lattice QCD application, tmLQCD.

The language enables the composition of preconditioners and iterative methods, and the compiler checks automatically the validity of application for each method. This makes possible a more systematic exploration of the algorithmic space: indeed, it removes from the physicists the burden of long and stressful validations of their new code since it will be automatically generated, then safer, and the time-to-market for a viable product will be much shorter. The QIRAL compiler generates OpenMP parallel code using BLAS or specialized versions of BLAS functions. Further hand-tuning is possible on the code generated by QIRAL, and we have shown that the performance on various multi-core architectures and on Xeon Phi accelerator it compares or outperforms the performance of a hand-tuned Lattice QCD application, tmLQCD.

Among the perspectives of this work, the automatic generation of a communication code for multi-node computation would enable to run Lattice QCD simulations on a larger scale. Besides, the fine tuning of the library functions used by QIRAL on different architectures, in particular their SIMDization, could be improved.

VII. Conclusion

The contribution of this paper is a new domain-specific language, QIRAL, for the automatic code generation of OpenMP codes for Lattice QCD simulations. QIRAL language offers to physicists the possibility to implement iterative methods and preconditioners, literally “from the book” using Fortran, or design new ones, and test them on large parallel shared memory machines or on accelerators such as the Xeon Phi. The language enables the composition of preconditioners and iterative methods, and the compiler checks automatically the validity of application for each method. This makes possible a more systematic exploration of the algorithmic space: indeed, it removes from the physicists the burden of long and stressful validations of their new code since it will be automatically generated, then safer, and the time-to-market for a viable product will be much shorter. The QIRAL compiler generates OpenMP parallel code using BLAS or specialized versions of BLAS functions. Further hand-tuning is possible on the code generated by QIRAL, and we have shown that the performance on various multi-core architectures and on Xeon Phi accelerator it compares or outperforms the performance of a hand-tuned Lattice QCD application, tmLQCD.

Among the perspectives of this work, the automatic generation of a communication code for multi-node computation would enable to run Lattice QCD simulations on a larger scale. Besides, the fine tuning of the library functions used by QIRAL on different architectures, in particular their SIMDization, could be improved.
