Abstract

Accurate prediction of ductile fracture of metallic materials requires sufficient understanding of the underlying micromechanical phenomena, especially if complex multiaxial and non-proportional loadings are to be considered. In this micromechanical study, real microstructures are submitted to realistic boundary conditions up to large plastic strains thanks to the combination of Laminography, Digital Volume Correlation and Finite Element Modelling. The obtained results evidence the effect of the microstructural heterogeneities on the ductile fracture process.

Introduction

A methodology developed for the study of the micromechanisms of ductile damage (void nucleation, growth and coalescence) for complex and heterogeneous microstructures up to large plastic strains is employed in this study. In this methodology, in-situ Synchrotron Radiation Computed Laminography (SRCL) (Centre des Matériaux, MINES ParisTech), Digital Volume Correlation (DVC) (Laboratoire de Mécanique et Technologie – École Normale Supérieure - Paris-Saclay) and Finite Element (FE) modelling (Centre de Mise en Forme de Matériaux, MINES ParisTech) are seamlessly coupled. In-situ SRCL tests provide three-dimensional images of the microstructure, and kinematic information is then obtained via DVC. A FE framework with advanced meshing capabilities is subsequently used in order to carry out micromechanical simulations thanks to the topological and kinematic information obtained by SRCL and DVC, respectively with the objective of studying the effect of the microstructural heterogeneities on the ductile fracture process.

Results

The described framework (SRCL-DVC-FE) was applied to a nodular cast iron specimen. This specimen has two laser-drilled holes of 1mm of diameter. Nodular cast iron was chosen because it provides strong contrast between the ferritic matrix and the graphite inclusions when observed via SRCL. This material also presents low levels of cohesive forces in the particle-matrix interface, which makes it possible to neglect them in the simulations. Since graphite inclusions are very soft with respect to the matrix, their mechanical contribution is not considered in the simulations, i.e., the particles are considered as voids. The mechanical behavior of the matrix is described with von Mises plasticity and isotropic hardening.

A section of the specimen along with the obtained plastic strain field is shown in Figure 1. Very good correspondence in the position of the deformed microstructural features is observed between the SRCL image and the simulation. Different localization bands with different orientations are predicted.

In Figure 2, the individual normalized void size evolution is presented for 53 voids in the domain. The line width of each curve in the figure is proportional to the corresponding initial void size. The absence of a clear trend between the initial void size and the final void growth hints at the complexity of the void growth due to the intervention of several microstructural variables.

Figure 2. Normalized void size evolution of 53 voids contained in the simulation domain

Conclusions

The micromechanisms of ductile damage were assessed via a SRCL-DVC-FE combined approach, with emphasis on the effect of the microstructural heterogeneities on the fracture process of a nodular cast iron specimen. Analyzing the effect of these heterogeneities can provide insight into the importance of usually simplified microstructural variables such as void shape and distribution, and help recognize limitations of void nucleation, growth and coalescence models, as well as behavior laws.

Conclusions

The authors would like to gratefully thank the French ANR for funding the COMINSIDE project.
