Abstract

We review the main design techniques of state observer design for continuous-time dynamical systems, namely algorithms which reconstruct online the full information of a dynamical process on the basis of partially measured data. Starting from necessary conditions for the existence of such asymptotic observers, we classify the available methods depending on the detectability/observability assumptions they require. We show how each class of observer relies on transforming the plant’s dynamics in a particular normal form which allows the design of an observer, and how each observability condition guarantees the invertibility of its associated transformation and the convergence of the observer. Finally, some implementation aspects and open problems are briefly discussed.

Keywords: observer design, observability, detectability, normal forms, Kalman observers, Kalman-like observers, observability grammian, extended Kalman filter, high-gain observers, KKL observers, nonlinear Luenberger observer

1. Introduction

In many applications, knowing the current state of a dynamical system is crucial either to build a controller or to obtain real time information on the system for decision-making or monitoring, see, e.g., [190, 126, 183] and references therein. A common way of addressing this problem is then to place some sensors on the physical system in order to have access to such information. In practice, however, not all the state variable are directly measurable: because we want to reduce the number of sensors to reduce costs, due to physical constraints, or simply because such a sensor does not exist. In this case, therefore, an estimation algorithm, often denoted as observers, is needed to process the incomplete and imperfect information provided by the sensors and thereby reconstruct a reliable estimate of the whole system state. Of course, such an algorithm can exist only if the measurements from the sensor somehow contain enough information to determine uniquely the state of the system, namely the system is observable. The number and quality of the sensors being often limited in practice due to cost and physical constraints, such estimation algorithms play a decisive role in a lot of applications.

Notation. \( \mathbb{R} \) (resp. \( \mathbb{N} \)) denotes the set of real numbers (resp. integers) and \( \mathbb{R}_{\geq 0} := [0, +\infty) \), \( \mathbb{N}_{\geq 0} := \mathbb{N} \setminus \{0\} \). A map \( \rho : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0} \) is a \( \mathcal{K} \)-map if \( \rho(0) = 0 \) and \( \rho \) is continuous and increasing, and a \( \mathcal{K}^\infty \)-map if it is also unbounded. A map \( \beta : \mathbb{R}_{\geq 0} \times \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0} \) is a \( \mathcal{KL} \)-map if for all \( t \in \mathbb{R}_{\geq 0} \), \( r \mapsto \beta(r, t) \) is increasing and for all \( r \in \mathbb{R}_{\geq 0} \), \( \lim_{t \to +\infty} \beta(r, t) = 0 \). For a matrix \( M \), \( \text{det}(M) := M + M^\top \), and for a positive definite matrix \( P \in \mathbb{R}^{n \times n}, \| \cdot \|_P \) denotes the norm associated to \( P \), namely \( \| x \|_P := \sqrt{x^\top Px} \) for \( x \in \mathbb{R}^n \).

1.1. Observation problem

We consider a general plant described by finite-dimensional continuous-time nonlinear dynamics of the form

\[
\dot{x} = f(x, t), \quad y = h(x, t),
\]

with state \( x \in \mathbb{R}^{d_x} \), output (or measurement) \( y \in \mathbb{R}^{d_y} \) and maps \( f, h : \mathbb{R}^{d_x} \times \mathbb{R} \to \mathbb{R}^{d_y} \) sufficiently regular, with \( d_x, d_y \in \mathbb{N}_{\geq 0} \). This paper aims at reviewing existing methods available in the literature to estimate online the full state \( x(t) \) of a solution to system (1) at time \( t \), based on the knowledge of the plant model described by the functions \( f, h \), and of the output \( y \) up to time \( t \). Generally in applications, we are interested in estimating only physically relevant solutions which are known to remain in a certain set \( \mathcal{X} \), often modelling known physical bounds on the states. Hence, the following assumption holds throughout the paper.

Standing Assumption. We consider sets \( X_0 \subset \mathcal{X} \subset \mathbb{R}^{d_x} \) such that any solution of (1) initialized in \( X_0 \) is defined on \( [0, +\infty) \) and remains in \( \mathcal{X} \) at all positive times.

The set \( X_0 \) does not need to be known for design, but will be used in the statement of the theorems to refer to the plant solutions that need to be estimated. On the other hand, the knowledge of \( \mathcal{X} \) may actively be used to design the estimation algorithms. Note that we restrict our attention to solutions defined on \( [0, +\infty) \) because we will mainly review asymptotic estimation methods. Otherwise, the estimate needs to converge in finite-time, before solutions cease to exist.

The system (1) encompasses a large variety of systems among which autonomous systems

\[
\dot{x} = f(x), \quad y = h(x),
\]

and systems with (known) input

\[
\dot{x} = f(x, u), \quad y = h(x, u),
\]
with \( u : \mathbb{R} \to \mathbb{R}^d \), although the treatise of [3] may present subtle differences compared to [1] in terms of causality and uniformity with respect to inputs.

1.2. Approaches for real-time state estimation

A first naive approach would be to simulate [1] simultaneously for a set of initial conditions and progressively removing from the set those producing an output trajectory “too far” from the witnessed \( y(t) \) (with the notion of “far” to be defined). If the output \( y \) determines a unique possible solution asymptotically, then the set of possible initial conditions shrinks to only one possible asymptotically. Otherwise, a certain distribution of possible initial conditions remains. However, the trade-off between amount of computations and estimation precision is typically not reachable, and the open-loop numerical integration of [1] is often not reliable in the presence of disturbances and model uncertainties. This path has nevertheless aroused a lot of research:

- either through stochastic approaches, considering random processes in the plant model [1], and following the probability distribution of the possible values of the state (see, e.g., [121]);
- or in a deterministic way, considering the presence of bounded disturbances in the dynamics [1], and producing a “set-valued observer” (see, e.g., [150]), “interval observer” (see, e.g., [105, 132, 164, 82]), or “norm observers” (see, e.g., [219]), guaranteed to contain the plant state.

Another natural approach is to proceed by a minimization approach (see, e.g., [239]), namely to solve online at each time

\[
\hat{x}(t) = \arg \min_{\hat{x}} \int_0^T |Y(\hat{x}_f, t; \tau) - y(\tau)|^2 d\tau
\]
or rather with finite memory

\[
\hat{x}(t) = \arg \min_{\hat{x}} \int_{t}^{T} |Y(\hat{x}_f, t; \tau) - y(\tau)|^2 d\tau,
\]

where \( Y(\hat{x}_f, t; \tau) \) denotes the output at time \( \tau \) of the solution to [1] going through \( \hat{x}_f \) at time \( t \). Some methods have been developed to solve this optimization problem online, in spite of its non-convexity and the presence of local minima (see, e.g., [6] for a survey of existing algorithms). Such algorithms are often denoted as finite-horizon observers and the theory is usually developed in the discrete-time context.

In this paper, the path we choose to follow is rather to look for a dynamical system, called observer, using the current value of the output \( y(t) \) and whose state is guaranteed to provide (at least asymptotically) enough information to asymptotically reconstruct the state of [1].

1.3. Asymptotic observers

An asymptotic observer takes the form

\[
\dot{\hat{x}} = T(\hat{x}, y, t), \quad \hat{x} = T(\hat{x}, y, t),
\]

with state \( \hat{x} \in \mathbb{R}^d \) for \( d \in \mathbb{N}_{>0} \) and maps \( T : \mathbb{R}^d \times \mathbb{R}^d \times \mathbb{R} \to \mathbb{R}^d, \ T : \mathbb{R}^d \times \mathbb{R}^d \times \mathbb{R} \to \mathbb{R}^d \) chosen such that the following holds.

**Definition 1.1.** The system [3] is an asymptotic observer for the system [1] if there exists \( \mathcal{Z}_0 \subset \mathbb{R}^d \) such that for any solution \( t \mapsto x(t) \) defined on \([0, +\infty)\) with \( x(0) \in \mathcal{X}_0 \), any solution \( t \mapsto \hat{x}(t) \) to [3] with \( \hat{x}(0) \in \mathcal{Z}_0 \) and input \( y(t) = h(x, t) \), is defined on \([0, +\infty)\) and verifies

\[
\lim_{t \to +\infty} |\hat{x}(t) - x(t)| = 0
\]

with \( \hat{x}(t) = T(\hat{x}(t), y(t), t) \).

In other words, \( \hat{x}(t) \) is an estimate of the current plant state and the error made with this estimation asymptotically converges to 0 as time goes to infinity.

In the next paragraph and in the rest of the paper, we will see that \( \hat{x} \) typically estimates a certain function of the state of the function \( T(x, t) \), which is injective with respect to \( x \), and with \( T \) representing its left-inverse. In the favorable case where \( T \) is the identity or a mere projection from \( \mathbb{R}^d \) to \( \mathbb{R}^d \), namely \( \hat{x} \) can directly be read from \( d \) components of \( \hat{x} \), we say that the observer is in the given coordinates.

The time-dependence in the mappings \( T(\cdot, y, \cdot) \) and \( T(\cdot, y, \cdot) \) allows to take into account the time dependence of the functions \( f \) and \( h \) in [1]. It may be removed for an autonomous system [2]. In case of a system with input [3], we will see that this time dependency may appear through the value \( u(t) \) at time \( t \), or a certain number of time derivatives of \( u(t) \) at time \( t \), or more generally model a dependence on the whole past trajectory of \( u \).

The output dependence in the mapping \( T(\cdot, y, \cdot) \) enables to cover the case where the knowledge of the output is used (explicitly or implicitly) to build the estimate \( \hat{x} \) from the observer state \( \hat{x} \). This sometimes allows to reduce the observer dimension, thus obtaining a reduced-order observer, see, e.g., [70].

An example is the so-called Immersion & Invariance approach (“I&I”) developed in [25, 127]. A drawback of those approaches is that the estimate \( \hat{x} \) then depends directly on \( y \) and is therefore more affected by measurement noise, while it is typically filtered through \( T \) in \( \hat{x} \). We remark also that under some mild conditions, the equivalence between the existence of a full-state observer and a reduced-order observer is well established, see, e.g., [214, 207]. In other words, when one obtains a full-state observer, then a reduced-order observer may be derived, and vice-versa.

Finally, we highlight that this article considers full-state observers in which the whole state \( x \) needs to be reconstructed from \( \hat{x} \). When only a certain part/function of the state needs to be estimated, one may consider the so-called functional observers, see, e.g., [123, 134].

1.4. Desired observer properties

Depending on the specifications, different additional properties can be imposed on the observer.

\(^1\) We say “any solution” because \( T \) may only be continuous, or even set-valued, and may admit several solutions. This is not a problem as long as any such solution verifies the required convergence property.
Exponential observer: If system (4) is an asymptotic observer and equation (5) is replaced by
\[ |\dot{x}(t) - x(t)| \leq c(\dot{z}(0), x(0)) \exp(-\lambda t) \] (6)
where \( c \) is a continuous positive function which estimates the overshoot of the observer and \( \lambda \) is the convergence rate.

Uniformly asymptotically stable observer: If system (4) is an asymptotic observer and equation (5) is replaced by
\[ |\dot{x}(t) - x(t)| \leq \beta(\dot{z}(0) - x(0), t) \] (7)
where \( \beta \) is a \( \mathcal{KL} \)-map. The observer is said Uniformly exponentially stable if the class \( \mathcal{KL} \)-map is \( \beta(s, t) = cs \exp(-\lambda t) \) for some positive real numbers \( c \) and \( \lambda \). Besides the attractivity described in (5), property (7) requires stability of the estimation error, namely the fact that for any \( \epsilon > 0 \), there exists \( \delta > 0 \) such that
\[ |\dot{x}(0) - x(0)| \leq \delta \implies |\dot{x}(t) - x(t)| \leq \epsilon, \quad \forall t \geq 0, \]
namely the estimation error remains arbitrarily small during the transient if the initial error is sufficiently small. Actually, (7) also requires the attractivity and stability to be uniform for any initial condition in \((x(0), \dot{z}(0)) \in X_0 \times Z_0\). This property is quite strong and may be relaxed in different ways depending on the context. In any case, remark that the stability imposes that the 0-error set \( x = \dot{x} \) is invariant by the dynamics. We will see that such stability properties may hold in certain well-chosen coordinates, and not in the initial \( x \)-coordinates.

Finite time observer: If system (4) is an asymptotic observer and equation (5) is replaced by
\[ |\dot{x}(t) - x(t)| = 0, \quad \forall t \geq t_c(\dot{z}(0), x(0)), \] (8)
where \( t_c \) is the convergence time depending on the initialization system and the observer in \( X_0 \times Z_0 \).

Uniform Finite time observer: If system (4) is a finite time observer and \( t_c \) is the convergence time uniform for all \((x(0), \dot{z}(0)) \in X_0 \times Z_0\).

Tunable observers: If we know a family of observers able to provide an arbitrarily small estimation error in an arbitrarily short time. More precisely, it implies that there exists a set of asymptotic observers such that for all \( \epsilon > 0 \) and for all \( t_d > 0 \) there exists an observer (in this set) \((\mathcal{F}, \mathcal{T})\) such that for any solution \( t \mapsto (x(t), \dot{z}(t)) \) to (4) defined on \([0, +\infty)\) with \((x(0), \dot{z}(0)) \in X_0 \times Z_0\) verifies
\[ |\dot{x}(t) - x(t)| \leq \epsilon, \quad \forall t \geq t_d, \] (9)

Robust observer: If system (4) is an asymptotic observer and admits an asymptotic gain in presence of disturbances on the plant dynamics (1). More precisely, there exist \( \bar{\nu} \in \mathbb{R}_{\geq 0} \cup \{+\infty\} \) and a \( \mathcal{KL} \)-map \( \rho \) such that, for any measurable and essentially bounded disturbance \( \nu = (\nu_x, \nu_y) : \mathbb{R} \to \mathbb{R}^d_x \times \mathbb{R}^d_y \), such that \(|\nu(t)| \leq \bar{\nu} \) for almost all \( t \geq 0 \), and for any solution \( t \mapsto x(t) \) to
\[ \dot{x} = f(x, t) + \nu_x, \quad y = h(x, t) + \nu_y, \]
defined on \([0, +\infty)\) and with \( x(0) \in X_0 \), the corresponding solution \( t \mapsto \dot{z}(t) \) to (4), with \( \dot{z}(0) \in Z_0 \) and input \( y \), is defined on \([0, +\infty)\) and verifies
\[ \limsup_{t \to +\infty} |\dot{z}(t) - x(t)| \leq \rho \left( \limsup_{t \to +\infty} |\nu(t)| \right). \] (10)

Again, more or less restrictive robustness properties may be stated depending on the context such as non-uniformity of \( \rho \) with respect to initial conditions, or some input-to-state-stability (ISS) conditions (see, e.g., [213][218]). Note that a uniformly asymptotically stable observer is a robust observer.

All in all, the role of an observer is to estimate in real time the plant state based on the knowledge of its output. This means that this signal somehow contains enough information to determine uniquely the whole state of the system. This brings us to the notions of observability or detectability, which characterize the necessary conditions that the plant must verify in order for an observer to exist. We will see that the strength of those conditions depend on the convergence/stability properties that are required from the observer.

2. Necessary conditions and a general sufficient condition for observer design

2.1. Necessary conditions for asymptotic observers

2.1.1. Detectability notions

For linear systems, it is well known that a detectability property is necessary for the existence of an observer. See, e.g., [154][20]. The same type of property can be defined for nonlinear systems as follows.

**Definition 2.1.** The system (1) is asymptotically detectable if any pair of solutions \( t \mapsto x_n(t) \) and \( t \mapsto x_b(t) \) to (1) initialized in \( X_0 \) and defined on \([0, +\infty)\) such that
\[ h(x_n(t), t) = h(x_b(t), t), \quad \forall t \geq 0, \]
verifies
\[ \lim_{t \to +\infty} \left| x_n(t) - x_b(t) \right| = 0. \] (12)

The property of asymptotic detectability says that when two solutions are not distinguishable from the output, they necessarily converge to each other asymptotically. This ensures one obtain a “good” asymptotic estimate no matter which initial condition we pick. The following result, which can be found for instance in [13], shows that asymptotic detectability is necessary for the existence of an asymptotic observer.

**Lemma 2.1.** If there exists an asymptotic observer for the system (1), then the system (1) is asymptotically detectable.
\textbf{Definition 2.2.} The system (1) is differentially detectable if there exists three positive real numbers \(0 < p \leq \bar{p}\) and \(q\) and a \(C^1\) matrix function \(P : \mathbb{R}^d \mapsto \mathbb{R}^{d \times d}\), such that \[ p I \leq P(x) \leq \bar{p} I, \quad \forall x \in \mathbb{R}^d, \] and\(^2\)
\[ \delta_i^T L_i P(x,t) \delta_i \leq -q \|x\|^2, \quad \forall (x, \delta_i, t) \in X \times \mathbb{R}^d \times \mathbb{R}_{\geq 0} \text{ such that } \frac{\partial h}{\partial x}(x(t), \delta_i) = 0. \] (15)

As studied in [205], this property establishes that the vector field \(f\) is contracting for a Riemannian distance (associated to the quadratic form \(\delta_i \mapsto \delta_i^T P(x(t)) \delta_i\) in the direction tangent to the level set of \(h\). Picking \(\delta_i \mapsto \delta_i^T P(x(t)) \delta_i\) as a Lyapunov function, it establishes that complete solutions to
\[ \dot{x} = f(x,t), \quad \delta_i = \frac{\partial f}{\partial x}(x(t)) \delta_i, \] initialized in \(X_0 \times \mathbb{R}^d\) and verifying
\[ \frac{\partial h}{\partial x}(x(t), \delta_i(t)) = 0, \quad \forall t \geq 0, \] satisfy
\[ \lim_{t \to +\infty} \|\delta_i(t)\| = 0. \] (18)

It is shown in [13], [15] that this property is linked to the existence of an observer giving exponential stability of some error set. Actually, for autonomous systems \((2)\) with \(X = X_0 = \mathbb{R}^d\), differentiability is necessary for the existence of an exponentially stable observer of the form
\[ \dot{\hat{x}} = \mathcal{T}(\hat{z}, y, t) = f(\hat{z}) + k(\hat{z}, y), \quad \hat{x} = \mathcal{T}(\hat{z}, y, t) = \hat{z}, \] made of a copy of the dynamics and an extra correction term.

\textbf{Lemma 2.2 ([14]).} If there exists a uniformly exponentially stable observer for the system \((2)\) in the form \((15)\) with \(Z_0 = \mathbb{R}^d\) and with \((f, h, k)\) having bounded first and second order derivatives then the system (1) is differentially detectable.

---

### 2.1.2. Observability notions

For linear systems, it is well-known that the ability to design an observer with arbitrary pole placement imposes an observability property. Various notions of observability can be defined for nonlinear systems. In its weakest version, "observability" means that \((1)\) must actually imply \(x_0 = x_0\), rather than asymptotic convergence in \((12)\), and "instantaneous observability" means that having \((1)\) on an arbitrarily small interval is enough to imply the equality.

\textbf{Definition 2.3.} The system (1) is instantaneously observable if for all \(t_d > 0\), any pair of solutions \(t \mapsto x_0(t)\) and \(t \mapsto x_0(t)\) initialized in \(X_0\) and defined on \([0, +\infty)\) such that
\[ h(x_0(t), t) = h(x_0(t), t), \quad \forall 0 \leq t < t_d, \] (20)
verifies \(x_0(t) = x_0(t)\).

The following result can be found in [13] for autonomous systems but extends readily to time-varying systems.

\textbf{Lemma 2.3.} If there exists a tunable observer for the system (1), then the system (1) is instantaneously observable.

In the particular case where \(f\) and \(h\) are analytical, the output \(y\) is an analytical function of time and the notions of observability and instantaneous observability are actually equivalent because two analytical functions which are equal on some interval are necessarily equal on their maximal interval of definition. Besides, for any initial condition, there exists \(t_y\) such that
\[ y(t) = \sum_{k=0}^{+\infty} \frac{\gamma(k)}{k!} t^k, \quad \forall t \in [0, t_y), \] and observability is thus closely related to the notion of differential observability defined in Section 5 which roughly says that the state is uniquely determined by the value of the output and of its derivatives (up to a certain order).

Actually, in observer design, one is more interested in estimating the current state \(x(t)\), based on the past measurements, than estimating its initial condition. Therefore, notions of \textit{backward distinguishability} (sometimes also called \textit{constructibility} or \textit{determinability}) typically appear as in Section 6 requiring that the current state be uniquely determined by the past outputs. Both are equivalent of course when solutions are unique, but not generally.

#### 2.1.3. Structural property on the observer

To summarize, the following implication may be obtained:

\begin{align*}
\text{Observer} & \quad \Rightarrow \quad \text{Deducibility.} \\
\text{Unif. exp. stable observer} & \quad \Rightarrow \quad \text{Differential detectability.} \\
\text{Tunable observer} & \quad \Rightarrow \quad \text{Instantaneous observability}
\end{align*}

In this survey, we will thus classify the observer designs available in the literature depending on which observability properties are required of the plant.

In order to justify the common spirit in which they are developed, it is interesting to recall another necessary condition
from [13]. Indeed, for an autonomous system $\dot{x}$, if there exists an asymptotic observer $\bar{z} (\mathbf{4})$ (without time-dependence) for $\dot{x}$ and a compact subset of $\mathbb{R}^d \times \mathbb{R}^d$ which is invariant by the dynamics $(f, \mathcal{F})$, then there exist compact subsets $C_x$, $C_\varepsilon$, and $C_\gamma$ of $\mathbb{R}^d$, and a closed set-valued map $T$ defined on $C_x$ such that the set

$$E = \{(x, \bar{z}) \in C_x \times C_\varepsilon : \bar{z} \in T(x)\}$$

is invariant, attractive, and verifies

$$\forall (x, \bar{z}) \in E, \quad T(\bar{z}, h(x)) = x.$$  

In other words, the pair made of the plant state $x$ (following the dynamics $f$) and the observer state $\bar{z}$ (following the dynamics $\mathcal{F}$) necessarily converges to the graph of some set-valued map $T$, and $T$ is a left-inverse of this mapping. Note that this injectivity is of a peculiar kind since it is conditional to the knowledge of the output, namely “$x \mapsto T(x)$ is injective knowing $h(x')$”. This result justifies the usual methodology of observer design for autonomous systems which consists in transforming, via a function $T$, the system into a form for which an observer can be made available, then design the observer in those new coordinates $z$ (i.e. find $\mathcal{F}$), and finally deduce an estimate in the original coordinates via inversion of $T$ (i.e. find $T^\mathcal{T}$). Actually, it follows that some observer properties such as stability or exponential convergence are obtained in the $z$-coordinates, namely on the error $\bar{z} - T(x)$, but are not necessarily preserved in the $x$-coordinates through the left-inversion of $T$, unless $T$ satisfies appropriate extra conditions (uniform injectivity, diffeomorphism, etc). However, this is generally acceptable since the crucial properties such as attractivity and robust asymptotic gain are typically preserved in the $x$-coordinates.

Note that in most approaches, the observer is designed from a (maybe time-varying) single-valued map $T$ because it is simpler to manipulate than a set-valued map. In the designs based on some contraction property presented in Section $\mathbf{3}$, $T$ is simply taken as the identity. For the high gain observers/differentiators presented in Section $\mathbf{5}$, $T(x, t)$ is obtained from the successive Lie derivatives of the output map $h$. In the case of the KKL observers presented in Section $\mathbf{9}$, $T$ is selected to transform the plant dynamics $\dot{x}$ into a particular Hurwitz form, namely as a solution to a PDE

$$\frac{\partial T}{\partial x}(x, t)f(x, t) + \frac{\partial T}{\partial t}(x, t) = \Lambda T(x, t) + \Gamma h(x, t)$$

where $\Lambda$ is a Hurwitz matrix.

2.2. Sufficient condition for observer design

Inspired by the previous section, we introduce the following sufficient condition on which all the designs presented in this paper are based on. See $\mathbf{44}$ Theorem 1.1] for its proof.

**Theorem 2.1.** Assume there exist an integer $d_x$, a $C^1$ map $T : \mathbb{R}^d \times \mathbb{R} \to \mathbb{R}^{d_x}$, and continuous mappings $F : \mathbb{R}^d \times \mathbb{R}^d \times \mathbb{R} \to \mathbb{R}^{d_x}$, $H : \mathbb{R}^d \times \mathbb{R} \to \mathbb{R}^{d_y}$, and $\mathcal{F} : \mathbb{R}^d \times \mathbb{R}^d \times \mathbb{R} \to \mathbb{R}^{d_y}$ such that

- $a)$ $T$ transforms the plant dynamics $\dot{x}$ into $\dot{\bar{z}}$

$$\dot{\bar{z}} = F(\bar{z}, H(z, t), t), \quad y = H(z, t),$$

i.e. for all $x \in \mathcal{X}$ and all $t \in [0, +\infty)$,

$$\frac{\partial T}{\partial x}(x, t)f(x, t) + \frac{\partial T}{\partial t}(x, t) = F(T(x, t), h(x, t), t), \quad h(x, t) = H(T(x, t), t).$$

- $b)$ $x \mapsto T(x, t)$ becomes uniformly injective after a certain time $\bar{t} \geq 0$, namely there exists a concave $\mathcal{K}$ function $\rho$ such that for all $(x_a, x_b) \in \mathcal{X} \times \mathcal{X}$ and all $t \geq \bar{t}$,

$$|x_a - x_b| \leq \rho \left(T(x_a, t) - T(x_b, t)\right).$$

- $c)$ The system

$$\dot{\bar{z}} = \mathcal{F}(\bar{z}, y, t)$$

is an asymptotic observer for $(23)$.

Then, there exists a map $T : \mathbb{R}^d \times \mathbb{R} \rightarrow \mathbb{R}^{d_x}$ such that for all $t \geq 0$, $z \mapsto T(z, t)$ is uniformly continuous and such that

$$T(T(x, t), t) = x, \quad \forall x \in \mathcal{X}.$$

Besides, $\mathbf{4}$ defined with the maps $(\mathcal{F}, T)$ is an asymptotic observer for system $\dot{x}$.

This result formalizes the design methodology presented in the previous section which consists in finding a (maybe time varying) uniformly injective change of coordinates $z = T(x, t)$ transforming $\dot{x}$ into a normal form $(23)$, then designing an observer $(26)$ for $(23)$, and finally find a left-inverse of $x \mapsto T(x, t)$ to recover an estimate in the initial $x$-coordinates.

**Remark 2.1.** Without the assumption of concavity of $\rho$ in item $b)$ of Theorem $\mathbf{2.7}$ it is still possible to show that $x \mapsto T(x, t)$ admits a continuous left-inverse $T$ defined on $\mathbb{R}^{d_x}$. But, as shown in [213] Example 4, continuity of $T$ is not enough to deduce the convergence of $\bar{z}$ from that of $\bar{z} :$ uniform continuity is necessary. Note that if $X$ is bounded, the concavity of $\rho$ is no longer a constraint, since a concave upper-approximation can always be obtained by saturation of $\rho$ (see [165] for more details).

**Remark 2.2.** By imposing stronger constraints on the mapping $T$ and on the observer $(26)$ for $(23)$, the properties that have been listed previously may be stated for the observer $\mathbf{4}$ obtained for system $\dot{x}$.

- If the observer $(26)$ for $(23)$ is uniformly asymptotically stable then the observer $\mathbf{4}$ for $\dot{x}$ is robust.

$^3$The expression of the dynamics under the form $F(z, H(z, t), t)$ can appear strange and abusive at this point because it is highly non unique and we should rather write $F\langle z \rangle$. However, we will see how specific structures of dynamics $F\langle z \rangle$ allow the design of an observer $\mathbf{4}$.

$^4$A function $\gamma$ is uniformly continuous if and only if $\lim_{n \rightarrow +\infty} |\gamma_n - x_0| = 0$ implies $\lim_{n \rightarrow +\infty} |\gamma(\gamma_n) - \gamma(x_0)| = 0$. 

5
• If the injectivity property (25) is strengthened into
\[ |x_a - x_b| \leq c|T(x_a, t) - T(x_b, t)| \]
for some positive real number c and if (26) is an exponential observer for (23) then the observer (4) is an exponential observer for (1).

• If a uniform continuity condition on T is added to the injectivity property (25), namely
\[ \rho(|T(x_a, t) - T(x_b, t)|) \leq |x_a - x_b| \leq \rho(|T(x_a, t) - T(x_b, t)|) \]
for some concave K-maps (\(\rho, \rho'\)) and (26) is a stable (resp. uniformly asymptotically stable) observer for (23) then the observer (4) is a stable (resp. uniformly asymptotically stable) observer for (1) when the observer initialization set verifies \( \mathbb{Z}_0 \subset T(X) \).

In this review paper, we attempt to make a list of the normal forms (23) available in the literature and their associated observer (26). We classify them depending of the kind of observability properties they require and the corresponding class of systems (1) that can be transformed into each form. All this is summed up in Table 1 at the end of the paper.

3. Observers from detectability conditions

In this section, observer designs based on the differential detectability condition are considered. Such observers are typically asymptotically stable and written directly in the given coordinates in the form (19), where the correction term k is such that \(k(x, h(x), t) = 0\). We thus rewrite it directly in a more conventional way
\[ \dot{x} = f(\hat{x}, t) + k(\hat{x}, y, t), \tag{27} \]
or sometimes
\[ \dot{x} = F(\hat{x}, y, t) + k(\hat{x}, y, t), \tag{28} \]
when \(F(x, h(x), t) = f(x, t)\) and if we employ an output injection directly in observer dynamics. All the question is now to find means to design the correction term k to ensure the observer convergence. This is the purpose of this section.

3.1. Finsler-like relaxation of differential detectability

To understand how the differential detectability property may be employed to design an observer, it may be enlightening to consider the case in which system (1) is linear, i.e. is in the form
\[ \dot{x} = Ax, \quad y = Cx, \quad x \in X = \mathbb{R}^d, \]
with A and C of appropriate dimension. The differential detectability property (see Definition 5.1) implies (when considering constant metric without loss of generality) the existence of a positive definite matrix \(P\) in \(\mathbb{R}^{d_x \times d_x}\), and a positive real number \(q\) such that for any positive definite \(R\) in \(\mathbb{R}^{d_x \times d_x}\)
\[ \delta_x^T [PA + A^T P] \delta_x \leq -q \delta_x^T P \delta_x, \]
\[ \forall \delta_x \in \mathbb{R}^{d_x} \text{ such that } \delta_x^T C^T R \delta_x = 0. \tag{29} \]

By Finsler’s lemma, given \(R\), this implication is equivalent to the existence of a positive real number \(k\) such that
\[ PA + A^T P - kC^T RC < 0. \tag{30} \]
In other words, the matrix \(A - kC^T RC\) is stable and consequently
\[ \dot{x} = Ax + kP^{-1} C^T R \]
defines an asymptotic observer. We recover the well-known Luenberger observer for detectable linear systems. In this section, our aim is to follow the same route to obtain converging observers.

3.2. A local observer assuming strong differential detectability

For nonlinear systems, the differential detectability property also implies the existence of an observer. However, without further assumption, the obtained observer is local. Indeed, going from the differential detectability property, i.e., the implication (15), toward a property in the form of (30) is possible but with a state and time dependent parameter. More precisely, assuming (15), it is possible to show the existence of a continuous function \(\rho : \mathbb{R}^d \times \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}\) such that
\[ L_f(x, t) \leq -\rho(x, t) \frac{\partial h}{\partial x}(x, t) + \frac{\partial h}{\partial x}(x, t) - q \rho(x), \]
\[ \forall (x, t) \in X \times \mathbb{R}_{\geq 0}. \tag{31} \]

When particularizing the result of [207] to the case in which there is only one output, the following result may be obtained for strongly differentially detectable autonomous system in the form (2).

Proposition 3.1. Consider an autonomous system in the form (2) with \(d_x = 1\). Assume that the couple \((f, h)\) is differentially detectable with \(X = X_0 = \mathbb{R}^d\), and assume that the function \(\rho\) in (31) is independent from time and there exists \(\kappa\) such that \(\kappa \geq \rho(x)\) for all \(x\). Assume moreover, that \(h\) has bounded first and second order derivatives then (27) with
\[ k(\hat{x}, y) = \kappa P(\hat{x})^{-1} \frac{\partial h}{\partial x}(\hat{x}) (y - h(\hat{x})), \tag{32} \]
is a local observer in the sense that there exists \(c_0\) such that for all complete solutions, if \(|\hat{x}(0) - x(0)| \leq c_0\) then (5) is satisfied.

Remark 3.1. Note also that the result in [207] is more general since a multidimensional output is considered. Moreover, the case in which \(X\) is only a subset of \(\mathbb{R}^d\) is considered, requiring a convexity property on \(X\). Moreover, the upper bounds on \(P\) and first and second derivatives of \(h\) are replaced by a boundedness assumption on the Riemannian Hessian of \(h\).

3.3. Toward regional observer assuming convexity of the output map

Assuming differential detectability only, the obtained observer is local since the initial error needs to be sufficiently small to ensure the observer convergence. In [205], a further
assumption is made allowing to obtain a semi-global observer. In order to introduce this one, notice that a $C^1$ function $P$ which satisfies (15) defines a complete riemannian metric on $\mathbb{R}^{d_x}$, for which we can define geodesics (straight line for Euclidean metrics).

**Definition 3.1.** Given $y$ in $\mathbb{R}$, the set $\{x \in \mathbb{R}^{d_x} : h(x) = y\}$ is said totally geodesic if any geodesic $\gamma$ satisfying

$$ h(\gamma(0)) = y, \quad \frac{dh}{ds} (\gamma(0)) = 0, $$

satisfies

$$ h(\gamma(s)) = y, \quad \forall s. $$

This assumption is related to a geodesic convexity property of these level sets (see [205]). It is trivially satisfied if for instance the output map is linear ($h(x) = Cx$ for some matrix $C$) and $P$ is constant. With this assumption, the following result is obtained in [205].

**Proposition 3.2.** Consider an autonomous system in the form (2) with $d_{\mathcal{Y}} = 1$. Assume that $\mathcal{X}$ is bounded. Assume moreover that the couple $(f, h)$ is differentially detectable. Finally, assume that the level sets of $h$ are totally geodesic then picking $\mathcal{Z}_0 = \mathcal{X}_0$ there exists a positive real number $\kappa$ such that (27) with (32) defines a uniformly asymptotically stable observer.

**Remark 3.2.** Again, the result in [205] is more general since a multidimensional output is considered and $\mathcal{X}$ is closed weakly geodesically and not necessarily bounded. However the result is semi-global in terms of the initial error: $\kappa$ has to be taken sufficiently large depending on the initial estimation error.

### 3.4. The case of a constant matrix function $P$

A case which has been deeply studied in the literature is the case in which the output map is linear

$$ h(x) = Cx, $$

for some matrix $C$ of appropriate dimension. In that case, to apply the former results, it suffices to find a constant matrix $P$ in $\mathbb{R}^{d_{\mathcal{Y}} \times d_{\mathcal{X}}}$ such that the system is differentially detectable with respect to this matrix $P$, i.e. such that

$$ \delta_x^\top \left[ P \frac{\partial f}{\partial x}(x, t) + \frac{\partial f}{\partial x} (x, t)^\top P \right] \delta_x \leq -q \delta_x^\top C \delta_x, $$

$$ \forall (x, \delta_x) \in \mathbb{R}^{d_x} \times \mathbb{R}^{d_x} \text{ such that } \delta_x^\top C^\top C \delta_x = 0. $$

Indeed, in that case, since $P$ is constant (Euclidean case), the level sets of $y = Cx$ are totally geodesic. Consequently, the former theorem applies and an observer may be obtained for a bounded $\mathcal{X}$. This result was previously published in the autonomous case in [152]. Assuming furthermore a global Lipschitz property (uniformly with respect to time) on $f$, it is possible to show that there exists $\kappa$ such that

$$ \left( \int_0^t \frac{\partial f}{\partial x} (\hat{x} + s(x - \hat{x}), y, t) + \frac{\partial k}{\partial x} (x + s(x - \hat{x}), y, t) \right) \ dx \right) \right) \times (x - \hat{x}). $$

and a observer may be obtained for $\mathcal{X} = \mathbb{R}^{d_x}$ as shown in [228]. The observer obtained is in the form (27) with

$$ k(\hat{x}, y, t) = \kappa P^{-1} C^\top (y - C \hat{x}). $$

Hence, one of the means to design an observer for nonlinear systems with linear measured output is to construct $P$ such that (35) holds.

Note that in this case and as shown in [55], a reduced order observer may be constructed (see also [207] for a Riemannian version of this result).

#### 3.5. Finding an Euclidean metric $P$ to obtain a contraction

With (34), it can be noticed that (27) with (36) satisfies

$$ \Re \left\{ P \left[ \frac{\partial f}{\partial x} (x, t) + \frac{\partial k}{\partial x} (x, y, t) \right] \right\} \leq -q I, \quad \forall (x, y, t). $$

This implies that (27) defines an exponential contraction in the sense that any two trajectories of the observer are exponentially converging to each other. Actually, contraction analysis is a common approach to design the correction term $k$ as summarized in the following proposition in which a time-variant metric is allowed.

**Proposition 3.3.** Consider a (possibly time-varying or controlled) system in the form (1) which satisfies

$$ f(x, t) = F(x, h(x), t), $$

for some smooth function $F$. If there exist $C^1$ functions $P : \mathbb{R} \mapsto \mathbb{R}^{d_{\mathcal{X}} \times d_{\mathcal{Y}}}$ and $k : \mathbb{R}^{d_x} \times \mathbb{R}^{d_x} \times \mathbb{R} \mapsto \mathbb{R}^{d_x}$, and positive real numbers $(q, p, \overline{P})$ such that

$$ k(x, h(x), t) = 0, \quad \forall (x, t) \in \mathbb{R}^{d_x} \times \mathbb{R}, $$

$$ P(t) + \Re \left\{ P(t) \left[ \frac{\partial f}{\partial x} (\hat{x}, y, t) + \frac{\partial k}{\partial x} (\hat{x}, y, t) \right] \right\} \leq -q I, \quad \forall (\hat{x}, y, t) \in \mathbb{R}^{d_x} \times \mathbb{R}^{d_x} \times \mathbb{R}, $$

$$ p I \leq P(t) \leq \overline{P} I, \quad \forall t \in \mathbb{R}. $$

Then (28) defines a uniformly exponentially stable observer.

**Proof.** Let $V(t) = \frac{1}{2} (x(t) - \hat{x}(t))^\top P(t)(x(t) - \hat{x}(t))$. Its time derivative is computed as

$$ V(t) = \frac{1}{2} (x - \hat{x})^\top P(t)(x - \hat{x}) $$

$$ + (x - \hat{x})^\top P(t) \left[ F(x, y, t) - F(\hat{x}, y, t) - k(\hat{x}, y, t) \right], $$

where the time-dependence of the variables $x$, $\hat{x}$ and $y$ has been omitted for compactness. Furthermore, with (39), we have for all $(x, y, t)$ in $\mathbb{R}^{d_x} \times \mathbb{R}^{d_x} \times \mathbb{R},$

$$ F(x, y, t) - F(\hat{x}, y, t) - k(\hat{x}, y, t) $$

$$ = \left( \int_0^t \frac{\partial f}{\partial x} (\hat{x} + s(x - \hat{x}), y, t) + \frac{\partial k}{\partial x} (x + s(x - \hat{x}), y, t) ds \right) $$

$$ \times (x - \hat{x}). $$
This gives, with (40) and the right hand side of (41),
\[ \dot{V}(t) \leq -\frac{q}{p} V(t), \]
from which, using (40) one more time, the conclusion holds.

Note that a similar proof of the former proposition can be found in [159]. Proposition 3.3 is the core of most of the publications related to observers, as shown in the forthcoming examples.

3.5.1. Designs based on LMI
In [23] is considered the case in which the dynamical system (1) is in the form
\[ f(x) = Ax + G\phi(\zeta, y, t), \quad h(x) = Cx, \quad \zeta = Mx, \quad (44) \]
where \((A, G, M, C)\) are matrices of appropriate dimensions and \(\phi\) is a smooth function with \(\zeta\) in \(\mathbb{R}^d\). The observers considered in [23] take the form
\[ \dot{x} = Ax + K(y - Cx) + G\phi(\hat{\zeta}, y, t), \]
\[ \dot{\hat{\zeta}} = M\hat{x} + E(\hat{y} - C\hat{x}), \quad (45) \]
where \(E, K\) are matrices in \(\mathbb{R}^{d \times d}\) and \(\mathbb{R}^{d \times d}\), respectively. We recognize an observer in the form (28). A sufficient condition to guarantee the convergence of the observer is to select the matrices \(E \) and \(K\) to ensure that the observer defines a uniform (with respect to \((y, t)\)) contraction. In other words, the goal is to find \(P, K\) such that
\[ (A - KC)P + P(A - KC) + Q \geq 0, \quad G^T P + WP(M - EC) = 0, \]
for some \((\text{fixed})\) diagonal matrix \(W > 0\). In such a case, the observer (45) with \(K, E\) satisfying the previous inequality is uniformly exponentially stable for system (1) with \(f, h\) of the form (44).

3.5.2. Structured nonlinearities
Finally, the conditions of Proposition 3.3 can be satisfied by imposing some structures on the nonlinearities. For instance, some approaches aim to find coordinates in which \(\varphi\) depends only on the measured output. This is the so-called linearization by output injection of observable dynamics, see Section 4.4.

A different approach is based on assuming that the nonlinearities satisfy an upper triangular structure, resulting in the so-called high-gain observer approach, see Section 5.

4. Observers from observability grammian
In this section, we consider the class of state-affine normal forms
\[ \dot{z} = A(y, t) z + \varphi(y, t), \quad y = C(t) z, \quad (48) \]
where \(A : \mathbb{R}^d \times \mathbb{R} \rightarrow \mathbb{R}^{d \times d}, \varphi : \mathbb{R}^d \times \mathbb{R} \rightarrow \mathbb{R}^d\) and \(C : \mathbb{R} \rightarrow \mathbb{R}^{d \times d}\). Note that (45) is not really affine in \(z\) since \(y\) depends on \(z\), but it is written so in order to highlight the dependency on the known signal \(y\) that is available for observer design. That is why the process of transforming a system into (48) is called in the literature linearization by output injection.

4.1. Observability grammian
When analysing the observability of a system of the form (48), one naturally comes across the notion of observability grammian. See, e.g., [70].

Definition 4.1. For a given signal \(t \mapsto y(t)\), the observability grammian associated to (48) on an interval \([t_0, t_1] \subset [0, +\infty)\) is the positive symmetric matrix defined by
\[
\mathcal{G}_\psi(t_0, t_1) = \int_{t_0}^{t_1} \Psi_\psi(t, \tau) \hat{C}(\tau)^T \hat{C}(\tau) \Psi_\psi(\tau, t_0) \, d\tau,
\]
where \(\Psi_\psi\) is the transition matrix associated to the linear dynamics \(\dot{\chi} = A(y, t) \chi\), namely the unique solution to
\[
\frac{\partial \Psi_\psi}{\partial \tau}(\tau, \tau) = A(y(\tau), \tau) \Psi_\psi(\tau, \tau), \quad \Psi_\psi(\tau, \tau) = I.
\]
Indeed, consider a pair of solutions $z_a$ and $z_b$ to system \([48]\) having same output $y$ for all $t \in [0, \bar{t}]$ for some $\bar{t} > 0$. Then, their difference $\chi = z_a - z_b$ verifies
\[
\dot{\chi} = A(y, t)\chi, \quad C(t)\chi(t) = 0, \quad \forall t \in [0, \bar{t}],
\]
and thus
\[
\chi(t) = \Psi_y(t, 0)\chi(0) = \Psi_y(t, 0) (z_a(0) - z_b(0)).
\]
Since $\|C(t)\chi(t)\|^2 = 0$ on the interval $[0, \bar{t}]$, it follows that
\[
(z_a(0) - z_b(0))^\top G_y(0, \bar{t}) (z_a(0) - z_b(0)) = 0.
\]
Therefore, the invertibility of $G_y(0, \bar{t})$ characterizes the observability of \([48]\) in time $\bar{t}$ for a given output signal $y$, namely the fact that two trajectories with same output $y$ over the interval $[0, \bar{t}]$ implies $z_a(0) = z_b(0)$ and thus $z_a = z_b$.

When $A$ is independent from $y$, so is the grammian, and any observability property is valid for any initial condition. Otherwise, one must take care to require uniformity with respect to any possible output signal $y$.

Putting aside the dependency on $y$, several observability properties can be defined depending on the “amplitude”, “uniformity”, “persistence”, etc of the grammian invertibility. For instance, Kalman’s well-known uniform complete observability \([125]\) requires the existence of $\alpha_1, \alpha_2 > 0$ and $\bar{t} > 0$ such that at all times,
\[
\alpha_1 I \leq G(t - \bar{t}, t) \leq \alpha_2 I.
\] (49)
The existence of $\alpha_2$ being guaranteed as long as $A$ and $C$ are bounded, this property is mainly about $\alpha_1$, namely the uniformity of the grammian invertibility over intervals of length $\bar{t}$. See Theorem \([41]\) below. If the time dependency of $A$ and $C$ comes through an input $u$, then such observability properties depend on this particular input. For instance, an input is said regularly persistent if it guarantees the existence of $\alpha_1$ at least after a certain time. See \([62]\) for more details.

### 4.2 Kalman or Kalman-like observers

The most famous observer used for state-affine systems is Kalman’s and Bucy’s observer presented in \([125]\) in a stochastic context, for linear time-varying systems with independent white-noise disturbances impacting the initial condition, the dynamics and the output. Their approach was to find an optimal estimate $\hat{z}(t)$ of $z(t)$ minimizing at each time $t$ the conditional expectation $E[\|\hat{z}(t) - z(t)\|^2 | y_0(t)]$ assuming known the covariance of each noise process.

On the other hand, parallel to the Kalman school, Kalman-like observers were introduced as an optimal solution to a deterministic optimisation problem \([63]\) \([111]\). More precisely, at each time $t$, the estimate $\hat{z}(t)$ is chosen as $\hat{z}(t) = \Psi_y(t, 0)\hat{z}^0$, where
\[
\hat{z}^0 = \arg \min \mathbb{E} e^{-\lambda t} \|\hat{z}_0 - z^0\|^2_{\Pi_0} + \int_0^t e^{-\lambda(t-\tau)} \|y(\tau) - C(\tau)\Psi_y(\tau, 0)\hat{z}^0\|_{\Pi_{\tau}} d\tau, \quad (50)
\]
for some positive matrices $\Pi_0$ and $R$.

In both cases, the miracle of linearity makes it possible to produce the optimal trajectory $\hat{z}(t)$ as the solution to an observer of the form
\[
\dot{\hat{z}} = A(y, t)\hat{z} + \varphi(y, t) + PI(t)^\top R^{-1}(t) (y - C(t)\hat{z}) \quad (51a)
\]
\[
\Pi = A(y, t)\Pi + PA(y, t)^\top - PI(t)^\top R^{-1}(t)C(t)\Pi + A\Pi + D(t)Q(t)D(t)^\top \quad (51b)
\]
or, equivalently, with $P^{-1} = \Pi$,
\[
\dot{\hat{z}} = A(y, t)\hat{z} + \varphi(y, t) + P^{-1}C(t)^\top R^{-1}(t) (y - C(t)\hat{z}) \quad (52a)
\]
\[
\dot{P} = -PA(y, t) - A(y, t)^\top P + C(t)^\top R^{-1}(t)C(t) \quad (52b)
\]
with
- in a Kalman design, $\lambda \geq 0$, $\Pi(0) = P^{-1}(0)$ (resp. $Q(t)$, resp. $R(t)$) the covariance matrix of the initial condition (resp. of the model noise, resp. of the output noise), and $D(t)$ the matrix describing how the model noise enters the dynamics at time $t$;
- in a Kalman-like design, $Q = 0$, $\lambda > 0$ modelling a (stabilizing) forgetting factor, $\Pi(0)^{-1} = P(0)$ (resp $R^{-1}$) describing the weight of the initial error and the output error in the optimized cost \([50]\), and thus the confidence in our initial guess and the output comparatively.

The main advantage of the Kalman-like design with $Q = 0$ is that it makes the dynamics of $\Pi^{-1}$ linear and explicitly solvable, with the expression of $\Pi^{-1}$ directly related to the observability (or more precisely determinability) grammian. This allows to derive lower- and upper-bounds on $\Pi^{-1}$ and follow a Lyapunov analysis with Lyapunov function $V = (\hat{z} - z)^\top \Pi^{-1}(\hat{z} - z)$ under a regular persistence assumption.

**Theorem 4.1** (Kalman-like design). Assume that there exist $\alpha_m \geq 0$, $\gamma > 0$, $\bar{t} > 0$ and $t_0 \geq t$ such that for any trajectory $t \mapsto z(t)$ of \([48]\) defined on $[0, +\infty)$ with output $y$, $t \mapsto A(y, t)$ is bounded by $\alpha_m$ and $G_y(t - \bar{t}, t) \geq \gamma I$. Then, for any $A > 2\alpha_m$ and any positive definite matrices $\Pi(0)$ and $R$, \([51]\) with $Q = 0$ is an asymptotic observer for \([48]\), with exponential convergence of the estimation error $\hat{z} - z$ after time $t_0$.

For a Kalman design, \([125]\) similarly requires boundedness of $A$ and uniform complete observability of the pair $(A, C)$, but additionally requires uniform complete controllability of the pair $(A, D)$ and $R$, $Q$ being positive definite with uniform upper- and lower bounds.

When the matrices $A$ and $C$ are constant, the invertibility of the observability grammian is equivalent to the so-called observability of the pair $(A, C)$, namely the fact that the matrix $O := \text{col}[C, CA, \ldots, CA^{d-1}]$ is full-rank \([70]\). In that case, one can implement the observer dynamics \([52a]\) with a constant gain $K = \Pi_0 C^\top R^{-1}$, where $\Pi_0$ is the asymptotic equilibrium of \([52b]\), which makes $A - KC$ Hurwitz. Note that this linear
observer with constant gain is also often called “Luenberger observer”, but we choose to keep this name for observers designed along Luenberger’s initial method [54] described in Section 5.

On the other hand, when the time-dependence in A and C comes from an input u, this input may be actively chosen to ensure the grammian condition and maximise observability, leading to the literature of active sensing [115, 114, 99, 200], to name a few. The position of the sensors itself may also be optimized, as in the literature of sensor positioning [233].

4.3. Extended Kalman Filter

The appeal of the Kalman filter mainly lies in its robustness and simplicity, since it is made of a copy of the dynamics and a correction gain obtained from a dynamic Riccati equation, whose parameters can be linked to physical quantities like noise covariance. That is why a very popular method in the industry (especially in the discrete-time formulation) consists in applying the Kalman filter also to nonlinear systems (1), by using the linearizations of f and h along the estimate ẑ in the Riccati equation. Such an approach is commonly denoted as Extended Kalman Filter (EKF) and takes the form

\[ \dot{\hat{x}} = f(\hat{x}, t) + \Pi C(\hat{x}, t) R^{-1}(y - h(\hat{x}, t)) \] (53a)

\[ \Pi = A(\hat{x}, t) \Pi + \Pi A(\hat{x}, t)^T + Q + \Pi \] (53b)

initialized at \( \Pi(0) = \Pi(0)^T > 0 \), with A, C defined as

\[ A(x, t) = \frac{\partial f}{\partial x}(x, t), \quad C(x, t) = \frac{\partial h}{\partial x}(x, t). \]

and Q some positive definite matrix.

Unfortunately, apart from particular uniformly observable triangular structures ([137, 109], see Proposition 5.3 below), only local convergence of the estimation error \( \hat{x} - x \) is ensured, under the additional ad-hoc assumption that the solution \( \Pi \) of the Riccati equation (53b) is uniformly bounded in time, namely there exist \( p, P > 0 \) such that

\[ pI \leq \Pi(t) \leq PI \quad \forall t \geq 0. \] (54)

See [196] for \( \lambda > 0 \) and [59] for \( \lambda = 0 \). However, the trajectory of \( \Pi \) depends on that of \( \hat{x} \) itself and the assumption (54) cannot be in general checked “a priori”, introducing therefore a loop in the stability analysis (the same issue appears in the discrete-time context [65, 217, 195]). An exception is [112], where an infinitesimal observability assumption is made on the plant, and not along the estimate. But convergence is still only local.

Recent contributions though, suggest that for controlled systems, the input could be actively chosen online to maximize the grammian associated to \( (A(\hat{x}, t), C(\hat{x}, t)) \), namely sufficiently excite the observability of the linearization along the known estimate trajectory \( \hat{x} \), in order to guarantee (54) holds and obtain semi-global convergence [203, 47].

4.4. Linearization by output injection

Once the community knew how to build an observer for the form (48), researchers attempted to characterize the class of nonlinear systems that could be transformed into such a form.

4.4.1. Constant observable pair (A, C)

The problem of (locally) transforming a nonlinear system into a linear one of the form (48) with a constant observable pair (A, C) via a diffeomorphism (with \( d_i = d_j \)) was first investigated in [139] for autonomous systems [2] and [136] for systems with inputs [9, 64] then gave conditions for the existence of a local (and global) immersion with \( d_i \geq d_j \), in the particular case of control affine systems. A vast literature followed on the subject, either developing algebraic algorithms to check the existence of a transformation or tools to explicitly find the transformation.

Actually, as noticed in [124], a system (1) can be transformed into (48) with constant observable pair (A, C) if and only if it can be transformed into

\[
\begin{aligned}
\dot{z}_1 &= z_2 + \varphi_1(z_1, t) \\
\vdots &
\end{aligned}
\]

\[
\begin{aligned}
\dot{z}_i &= z_{i+1} + \varphi_i(z_1, t) \\
\dot{z}_m &= \varphi_m(z_1, t)
\end{aligned}
\]

if \( d_i = 1 \) or blocks of this form otherwise. This is therefore more restrictive than the triangular forms of Section 5 where each \( \varphi_i \) is allowed to depend on \( z_1, ..., z_i \). In particular, for autonomous systems, [124, 58] show that this is equivalent to finding for each output, a change of output \( \psi : \mathbb{R} \rightarrow \mathbb{R} \) and maps \( \varphi_i \) solution to the characteristic equation

\[ L_j \tilde{h} = L_j^{-1} \varphi_1 \circ \tilde{h} + L_j^{-2} \varphi_2 \circ \tilde{h} + \ldots + L_j \varphi_{j-1} \circ \tilde{h} + \varphi_j \circ \tilde{h} \]

with \( \tilde{h} = \psi \circ h \), which does not always admit solutions.

Along the history of linearization, we may also mention some generalizations such as [129], where the function \( \varphi \) is allowed to depend on the derivatives of the input and later on the derivatives of the output in [78], or [106, 197] where it is proposed to use an output-depending time-scale transformation. But generally the existence of the transformation is difficult to check and involves tedious symbolic computations, which do not always give the transformation itself. Even when they do, its validity is often local and its injectivity on \( X \) not guaranteed.

4.4.2. Time-varying pair (A, C)

In parallel, [97] studied the linearization problem by allowing A and C in (48) to depend on time/the input. This led to the still restrictive finiteness criterion of the observation space, which roughly says that the linear space containing the successive derivatives of the output along any vector field of the type \( f(\cdot, u) \) is finite. Later, [110, 54] also allowed A to depend on the output \( y \) to broaden the class of concerned systems. But those systems remain difficult to characterize because there are often many possible parametrizations via the output.

5. Observers from differential observability

5.1. Differential observability and normal forms

Consider an autonomous single-output system of the form (2), i.e.,

\[ \dot{x} = f(x), \quad y = h(x). \]
$x \in \mathbb{R}^d$, $y \in \mathbb{R}$, in which the functions $f, h$ are supposed to be sufficiently differentiable. We have the following definition of differential observability, which is based on the analysis of the time-derivatives $\dot{y}, \ddot{y}, \ldots, y^{(k)}$, $k \geq n - 1$, of the output $y$, derived from the notion of infinitesimal observability introduced in [102] Definition 2.4.

**Definition 5.1.** The system (1) is said to be:

- weakly differentially observable if there exists $d_c \in \mathbb{N}$ such that the mapping $T : \mathbb{R}^d, \rightarrow \mathbb{R}^d$,

$$T(x) = \begin{pmatrix} h(x) \\ L_fh(x) \\ \vdots \\ L_f^{d_c-1}h(x) \end{pmatrix}$$ (55)

is injective on $X$;

- strongly differentially observable if the previous condition holds, and moreover the mapping $T$ is full rank for all $x \in X$.

**Remark 5.1.** For a linear system, the mapping $T$ defined in (55) with $d_c = d$, is computed as $T(x) = Ox$ where $O$ is the observability matrix $O := \text{col}[C, CA, \ldots, CA^{d_c-1}]$. Weak and strong differential observability therefore coincide with the standard rank test for the matrix $O$.

Under weak differentiability, if $T$ defined in (55) is actually uniformly injective on $X$ in the sense of Theorem 2.1, for instance if $X$ is compact, then $T$ admits a uniformly continuous left-inverse $T'$ defined on $\mathbb{R}^d$. Then, a direct consequence is that system (1) can be transformed, using $z = T(x)$, into a system of the form

$$\dot{z} = Az + \varphi(z), \quad y = Cz.$$ (56)

with $z \in \mathbb{R}^d$, and where $(A, \varphi, C)$ is a triplet, often denoted in prime form, defined as $\varphi(z) = \left(0, \ldots, 0, \varphi_d(z)\right)^T$ and

$$A = \begin{pmatrix} 0 & 1 & \cdots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & \cdots & 1 \\ 0 & \cdots & \cdots & 0 \end{pmatrix}, \quad C = \begin{pmatrix} 1 & 0 & \cdots & 0 \end{pmatrix},$$ (57)

and the continuous function $\varphi_d : \mathbb{R}^d \rightarrow \mathbb{R}$ is defined as $L_f^dh \circ T$. A system of the form (56) is also said to be in canonical observability form, or phase-variable form or simply normal form. See, e.g., [103]. One of the peculiarities of such a normal form is its lower-triangular structure and in particular its chain of integrator form in which each $i$-th component of the state $z$ represents the $(i - 1)$-th time derivative of the measured output $y$. As we shall see in Section 5.2, the interest of such lower-triangular forms relies on the systematic design of differentiators able to reconstruct the state $z$ with an arbitrarily fast exponential rate of convergence (in this case, we talk about high-gain observers, see Section 5.2) or finite-time convergence (following sliding-mode or homogeneous approaches, see Section 5.3).

While for autonomous systems, Definition 5.1 provides sufficient and necessary conditions to obtain a normal form, the extension to time-varying systems (1), resp. controlled systems (5), is more involved because the presence of time $t$, resp. inputs $u$, may destroy the observability properties of the system. Indeed, starting from [100], a lot of work has been done in order to establish the existence of state transformations, dependent or independent on the input $t$, resp. $u$, to obtain generalized lower-triangular forms for which high-gain observer design theory may be applied. See, e.g., [234, 96, 185, 201, 51] and references therein. For instance, one can allow the state transformation (55) to be $t$ dependent (resp. $u, \dot{u}, \ddot{u}, \ldots$ dependent), so that to obtain an injective map $T_d(x)$ (resp. $T_{t}(x)$), uniform in time (resp. in $u$ and its derivatives) transforming the time varying system (1) (resp. controlled system (3)) into a system of the form (56) in which the function $\varphi$ is now $t$ (resp. $u$) dependent. See, e.g., the phase-variable form in [234] or [103] Section 2.2. A similar equivalent notion is also that of complete uniform observability introduced in [222].

Being the focus of this paper the design of observers, we state the following definition that generalizes the form (55) for time-varying systems (1).

**Definition 5.2.** The system (1) admits a triangular normal form if there exists a mapping $T : \mathbb{R}^d \times \mathbb{R} \rightarrow \mathbb{R}^d$, (uniformly) injective in $X$, transforming system (1) in the sense of Theorem 2.1 into a system of the form (29) with an output map of the form

$$y = H(z_1, t)$$ (58)

and where the function $F = (F_1, \ldots, F_d)$ satisfies the lower triangular structure,

$$\frac{\partial F_j}{\partial z_i}(z, y, t) = 0, \quad j > i + 1, \quad \forall (z, y, t).$$ (59)

Note that for controlled systems (3), it suffices to replace $t$ in (59) with $u$ (and possibly its time-derivatives $\dot{u}, \ddot{u}, \ldots$), see, e.g., [103] Section 3.2.

For input-affine systems of the form

$$\dot{x} = f(x) + g(x)u, \quad y = h(x),$$ (60)

with scalar input $u \in \mathbb{R}$ and output $y \in \mathbb{R}$, necessary and sufficient conditions to admit an autonomous transformation into a triangular normal form (without output injection) have been given in [100] Section 4) or Theorem 4.1 in [103] Section 3.4). In particular, if (60) is observable for any input (uniform observability) and the autonomous part of (60) is strongly differentially observable of order $d$, then $T$ defined in (55) transforms (60) into (59), in which the functions $F_i$ are smooth and input affine and $H(z_1, t) = z_1$. The possibility of extending this result to any uniformly observable system in the form (60) with higher order of differential observability and less regularity of $F$ has been studied in [51] but is still not fully characterized.
Another special case of the form (59) is when the system can be written in the form
\[
F(z, y, t) = A(y, t)z + \varphi(y, z, t) \\
y = C(t)z + D(t)
\]
where the functions \(A, \varphi\) have the structure
\[
A(y, t) = \begin{bmatrix} 0 & a_1(y, t) & \cdots & 0 \\
0 & \ddots & \ddots & \vdots \\
0 & \cdots & a_{d-1}(y, t) & 0 \\
\end{bmatrix},
\]
\[
\varphi(z, t) = \begin{bmatrix} \varphi_1(y, t) \\
\varphi_2(y, z, t) \\
\vdots \\
\varphi_d(y, z_1, \ldots, z_d, t) \\
\end{bmatrix}.
\]
See, for instance, [56].

We finally remark that extensions to the multiple-output case allow to obtain block-triangular forms in which each block has a triangular form satisfying (59). For compactness, we refer, for example, to [100, 234, 225, 86, 79] and we limit the exposition of Section 5 to the single-output case.

5.2. High-gain observers

5.2.1. General construction

The use of high-gain observers for state-estimation of nonlinear systems first appeared at the end of the 80’s in a different number of contemporary works [83, 225, 86, 79]. One of the main features of high-gain observers is its “tunability property” which is typically controlled by one single scalar parameter. Such a fundamental property allowed this class of observers in nonlinear control theory to address the problem of output feedback stabilization (see also Section 7). We refer to [130] and references therein for an extensive bibliography on the topic.

The high-gain observer construction is based on the fact that for the triangular normal form, it is possible to follow the strategy described in Section 1.5 and Proposition 3.3 to construct an observer. More precisely, it is possible to construct a metric \(P : \mathbb{R} \mapsto \mathbb{R}^{d \times d}\) and a smooth correction term \(k\) such that
\[
k(z, H(z), t) = 0, \quad \forall (z, t) \in \mathbb{R}^d \times \mathbb{R},
\]
\[
P(t) + \text{He} \left\{ P(t) \left[ \frac{\partial F}{\partial z}(z, y, t) + \frac{\partial k}{\partial z}(z, y, t) \right] \right\} \leq -qI,
\]
\[
\text{∀}(y, z, t) \in \mathbb{R}^{d \times d} \times \mathbb{R}^d \times \mathbb{R},
\]
\[
P(t) \leq P(t) \leq \bar{P} I, \quad \forall t \in \mathbb{R}.
\]
With Proposition 3.3 it implies that
\[
\dot{\hat{z}} = F(\hat{z}, y, t) + k(\hat{z}, y, t),
\]
is a uniformly exponentially stable observer in the \(z\) coordinates. Hence, with
\[
\dot{\hat{z}} = T(\hat{z}, t)
\]
in which \(T\) is uniformly continuous left inverse of \(T\), defines an asymptotic observer for the given coordinates.

To construct \(P\) and \(k\) such that (62), (63), (64) hold, various results have been obtained. They are all based on the same two steps designs. First of all, let us denote
\[
a_i(z, y, t) = \frac{\partial F}{\partial z_i}(z, y, t), \quad 1 \leq i \leq d,
\]
\[
b_j(z, y, t) = \frac{\partial F}{\partial z_j}(z, y, t), \quad 1 \leq j \leq i,
\]
\[
c(z, t) = \frac{\partial H}{\partial z_1}(z_1, t).
\]
We have the decomposition
\[
\frac{\partial F}{\partial z}(z, y, t) = A(z, y, t) + B(z, y, t), \quad \frac{\partial H}{\partial z}(z_1, t) = C(z_1, t)
\]
where (forgetting the dependence in \((z, y)\))
\[
A(t) = \begin{bmatrix} 0 & a_1(t) & \cdots & 0 \\
0 & \ddots & \ddots & \vdots \\
0 & \cdots & a_{d-1}(t) & 0 \\
\end{bmatrix},
\]
\[
B(t) = \begin{bmatrix} b_1(t) & 0 & \cdots & 0 \\
\vdots & \ddots & \vdots & \vdots \\
b_{d-1}(t) & \cdots & b_{d-1}(t) \\
\end{bmatrix},
\]
\[
C(t) = \begin{bmatrix} c_1(t) & 0 & \cdots & 0 \\
\end{bmatrix}.
\]
The two designs steps for high-gain observer construction can be given as follows.

**Step 1:** Construct a preliminary correction term \(k_0\) only for \(A\). The problem reduces in finding \(P\) and \(k_0\) such that (62) and (64) hold and also
\[
P(t) + \text{He} \left\{ P(t) \left[ A(t) + \frac{\partial k_0}{\partial z}(z, y, t) \right] \right\} \leq -qI,
\]
\[
\forall (y, z, t) \in \mathbb{R}^{d \times d} \times \mathbb{R}^d \times \mathbb{R}.
\]

For instance, in the case in which \(A\) is constant (as in the prime form or the uniformly observable context), this steps can be simply followed by pole placement for linear dynamics and selecting \(P\) constant.

**Step 2:** Increase the robustness via high-gain scaling. If one compare (60) and (63), the difference comes from the \(B\) term which is lower triangular according to (65). As it will be shown in the following, a typical global Lipschitz property allows to modify \(k_0\) and \(P\) to cope with this extra term. Note that if \(X\) is bounded and if the system admits a locally Lipschitz triangular normal form, it may be possible to extend it into a globally Lipschitz triangular norm outside of \(T(X)\). In practice, this extension is obtained by saturation.

Two main types of methods have been developed, both of them follows this two steps design: the case in which the metric \(P\) is constant (also called Luenberger-like High-gain Observers) and the case in which \(P\) is time varying (also denoted Kalman-like High-gain Observer or Extended-Kalman-like High-gain Observer).
5.2.2. With a constant metric $P$

For step 1: The case of a constant metric is the most popular one (see 69, 101, 79). When the $A$ matrix in (69) is constant, namely takes the form (72), it suffices to select $K = (k_1, \ldots, k_d)\top$, with $k_i$ coefficients of a stable polynomial, so that the matrix

$$A - KC = \begin{pmatrix}
-k_1 & 1 & 0 \\
\vdots & \ddots & \vdots \\
-k_d & \cdots & 1
\end{pmatrix}$$

is Hurwitz, and $P$ solution of the Lyapunov equation $\text{He}(P(A - KC)) \preceq -qI$. In its most general form, namely for non-constant matrices $A$, the following lemma due to W. Dayawansa can be found in 79 Lemma 2.1 p. 96 and in 120 Section 7.4A.

**Lemma 5.1** (103). Consider $A$ and $C$ defined in (69). Suppose there exist $0 < a < \bar{a}$ and $0 < c < c\bar{\tau}$ such that

$$a < \frac{\partial F_i(z, y, t)}{\partial z_i} < \bar{a}, \quad c < \frac{\partial H(z, y, t)}{\partial z_i} < \bar{c}, \quad \forall t.$$  \hfill (71)

Then, there exists a vector $K$ in $\mathbb{R}^d$ and a positive definite matrix $P$ in $\mathbb{R}^{d \times d}$, both depending only on $(a, \bar{a}, c, \bar{c})$, such that

$$\text{He}(P[A(t) - KC(t)]) \preceq -qI, \quad \forall t.$$  \hfill (72)

For step 2: Employing a high-gain scaling defined with

$$D_\ell := \text{diag}(\ell, \ell^2, \ldots, \ell^d),$$  \hfill (73)

where $\ell$ is the so-called high-gain parameter\footnote{The high-gain parameter is sometimes denoted, in literature, with $\ell = \frac{1}{\epsilon}$ and $\epsilon$ to be taken small enough, see, e.g., 130.}, it is possible to amplify the robustness of the correction terms to cope with Lipschitz nonlinearities. Based on this approach, the following Proposition is obtained, see, e.g., 103.

**Proposition 5.1.** Assume that the system (1) admits a triangular normal form (see Definition 5.2) with the mappings $F$ and $H$ which satisfy for all $(z, y, t)$ in $\mathbb{R}^d \times \mathbb{R} \times \mathbb{R}$

$$a < \frac{\partial F_i(z, y, t)}{\partial z_i} < \bar{a}, \quad c < \frac{\partial H(z, y, t)}{\partial z_i} < \bar{c}, \quad \forall t,$$  \hfill (74)

$$\frac{\partial F_j(z, y, t)}{\partial z_i} < \bar{b}, \quad j \leq i, \quad \forall t,$$  \hfill (75)

for some positive real numbers $(a, \bar{a}, c, \bar{c}, \bar{b})$. Then, with $K$ in $\mathbb{R}^d$ obtained from Lemma 5.1 there exists $\ell^\star$ such that for all $\ell > \ell^\star$, the system (65), (66) is a robust tunable asymptotic observer with

$$k(\hat{z}, y, t) = D_\ell K[y - H(\hat{z}, t)]$$  \hfill (76)

and $D_\ell$ defined as in (73).

The main feature of observer (65), (66) is that the high-gain parameter $\ell > 0$ is chosen large enough compared to the Lipschitz bound (102) (see, e.g., 113, Section 3). The following bound then holds for the estimation error in the $z$ coordinates

$$|z(t) - \hat{z}(t)| \leq c_1 \ell^{d-1} \exp(-\ell c_2) |z(0) - \hat{z}(0)|, \quad \forall t,$$  \hfill (77)

for some constants $c_1, c_2$ independent from $\ell$. From this inequality, we obtain that the high-gain observer (65), (66) is uniformly exponentially stable in the $z$ coordinates. It is moreover robust and a tunable observer in the given conditions (see Section 1.4) since its convergence rate can be arbitrarily increased by augmenting the high-gain parameter $\ell$. Note, however, that a typical drawback of such a construction is the fact that the overshoot increases in $\ell^{d-1}$, and usually denoted as “peaking phenomenon”.

Combining Lipschitz conditions, an LMI-design mixing the aforementioned paradigm and the results in Section 3.5 can be also obtained in order to obtain less restrictive conditions by following 237.

When the mapping $F$ is no longer Lipschitz, the high-gain observer no longer ensures asymptotic convergence, but practical convergence may be guaranteed under some conditions on the H"older powers or boundedness of each nonlinearity, see, e.g., 49. Otherwise, more general homogeneous convergence terms can be used, as detailed in Section 5.3.

5.2.3. Kalman-like high-gain observers

For step 1: Another approach to design a correction term for $A$ is to follow the approach obtained from the observability grammian given in Section 4. In order to do so, one needs to consider the particular case in which $A$ and $C$ depend only on known signals (i.e. $y$ and $t$ or $u$ but not $z$) and can be employed to update dynamically $P$. Moreover, the pair $(A, C)$ needs to be observable in the sense that the observability Grammian $G_\ell$, of the system (see Definition 4.1)

$$\dot{x} = A(y, t)x, \quad y = C(t)x,$$  \hfill (78)

needs to be lower bounded in a particular manner. We have the following result, see, e.g., 53.

**Lemma 5.2.** Assume that there exists a positive real number $\bar{a}$ such that $|a_i(y, t)| \leq \bar{a}$ for all $y, t$. Assume moreover that there exists $\ell^\star$ that for all $\ell > \ell^\star$ and all $t \geq \frac{1}{\ell}$

$$G_\ell(t) \left(1 - \frac{1}{\ell} t\right) \geq c_{\ell} D_\ell^2,$$  \hfill (79)

with $D_\ell$ defined as in (73). Then, for any $\lambda \geq 2\bar{a}$ there exists $P$ and $\bar{P}$ such that for all $\ell > \ell^\star$ the solution to

$$P(t) = \ell \left(-AP(t) - A(y, t)\top P(t) - P(t)A(y, t) + C(t)\top C(t)\right)$$  \hfill (80)

initialized at $P(0) = P(0)\top > 0$ satisfies (64).

The grammian condition may be referred to as instantaneous uniform complete observability, since it requires lower boundedness for arbitrary small time.
For step 2: Again, for the second step, assuming a global Lipschitz property, it is possible to cope with the nonlinearities.

**Proposition 5.2.** Assume that the system (1) admits a triangular normal form with a vector field F such that A and C given in \((68),(69)\) are independent of \(z\), and

\[
\frac{\partial F_j}{\partial z_j}(z,y,t) < \bar{b}, \quad j \leq i,
\]

and the assumptions of Lemma 5.2 hold, then there exists \(\ell^*\) such that for all \(\ell > \ell^*\), the system \((65),(66),(78)\) is a robust tunable asymptotic observer with

\[
k(\dot{z},y,t) = D_P P^{-1}(y-C(t)\dot{z})
\]

and \(D_P\) defined as in \((73)\).

As highlighted in Proposition 5.2, the gain of the high-gain observer \((65),(66)\), is obtained from the solution of a differential Lyapunov matrix equation \((78)\) similar to the one of \((52)\). In the case in which \(A,C\) in \((78)\) are constant, we recall also the works \([71],[118]\) and the early work \([101]\) in which the asymptotic solution to \((78)\), \(P_\infty = \lim_{t\to\infty} P(t)\) is employed.

In \([103]\), another version of the Kalman-like high-gain observer is given in which the matrix function \(B\) is also employed in the update law of \(P\) and where \(A\) and \(C\) are assumed to be constant. We briefly recall the main result.

**Proposition 5.3.** Assume that the system (1) admits a triangular normal form with a vector field F such that A and C given in \((68),(69)\) are constant and of the form \((57)\) and

\[
\frac{\partial F_j}{\partial z_j}(z,y,t) < \bar{b}, \quad j \leq i,
\]

then there exists \(\ell^*\) such that for all \(\ell > \ell^*\), the system \((65),(66)\) is a robust tunable asymptotic observer with

\[
k(\dot{z},y,t) = P(t)^{-1}(y-C(t)\dot{z})
\]

where

\[
P(t) = -\left(A^T + B(\dot{z},t)^T\right) P(t) - P(t) \left(A^T + B(\dot{z},t)\right) + C^T C - P(t) D_P^T D_P(t),
\]

initialized at \(P(0) = P(0)^T > 0\), and \(D_P\) defined as in \((73)\).

In that case, the design of the gain \((65)\) of the high-gain observer \((65),(66)\) is obtained from the solution of a differential Riccati matrix equation \((83)\) which is exactly the same as the Extended Kalman Filter. For this reason, this observer is named the Extended Kalman like High-gain Observer.

5.2.4. Adapting the high-gain parameter and dynamics scaling

The idea of dynamically updating the high-gain parameter has been investigated by many researchers. The motivation for this is twofold: for qualitative purpose to reduce the size of the gain (see for instance \([92]\)), or to allow unknown or time-dependant Lipschitz constants.

- For instance, Lipschitz bounds of the form

\[
\frac{\partial F_j}{\partial z_j}(z,y,t) < \bar{b}(y,t), \quad j \leq i,
\]

where now \(\bar{b}(y,t)\) is a continuous function have been considered in \([182]\) or \([141]\). In that case the prototypical high-gain parameter updating law takes the form

\[
\ell = \ell(c_1(c_2 - \ell) + c_3\bar{b}(y,t)), \quad \ell(0) > c_2,
\]

for some positive real number \((c_1,c_2,c_3)\). The idea behind such a design is that \(\ell\) dynamically adapts to the Lipschitz bound \((84)\) with a Riccati differential equation.

- In \([66],[144],[7]\) the Lipschitz bound is unknown. The idea is then to employ a strictly increasing high-gain parameter. Note that in this case, the obtained observer may not be robust.

- Adaptation has also been employed in combination with the Kalman-like high-gain observer given in Proposition 5.3, see, e.g. \([58]\).

5.3. Homogeneous correction terms

5.3.1. Homogeneity to allow non locally Lipschitz normal form

Homogeneous observers are extensions of high gain observers able to cope with non-Lipschitz functions. They already have an old history and it can be traced back to the work of Arie Levant (see, e.g., \([145],[146],[233],[147],[186],[188],[158],[175],[17],[19],[49]\)).

The homogeneous correction terms of degree \(r\) in \([-1,\frac{1}{d_\ell-r}]\) denoted \(k_{\text{Hom}} = (k_{\text{Hom},1},\ldots,k_{\text{Hom},d_\ell})\) takes the form

\[
k_{\text{Hom},i}(s) = c_i \text{sign}(s)|s|^{\omega_i}, \quad r_i = 1 - r(d_\ell - i),
\]

where \(c_i\) are gains to be tuned and \(\text{sign}(s)\) is a set-valued map defined as

\[
\text{sign}(s) = \begin{cases} 
1 & \text{if } s > 0, \\
[-1,1] & \text{if } s = 0, \\
-1 & \text{if } s < 0,
\end{cases}
\]

which is upper semi-continuous with nonempty, compact and convex values. In \((85)\), \(r = (r_1,\ldots,r_{d_\ell+1})\) is a vector in \(\mathbb{R}^{d_\ell+1}\), called weight vector. For instance, for \(r = 1\) and \(d_\ell = 2\), we obtain

\[
k_{\text{Hom},1}(s) = c_1 \text{sign}(s)|s|^\omega, \quad k_{\text{Hom},2}(s) = c_2 \text{sign}(s),
\]

recovering the gains of the well-known two-order sliding-mode observer, see, e.g., \([145],[12]\) and references therein. For the case \(r = -1\), the observer dynamics with the correction term \((85)\) must be understood as a differential inclusion. When \(r = 0\), we recover a linear correction terms as the one given in Lemma 5.1.

The construction strategy in the homogeneous case is the same two steps design as the one previously given. However, since our aim is to consider possibly non differentiable functions we do not follow the differential framework. So in the
following, we assume the system (1) admits a continuous triangular normal form in the form (61) with constant matrices C and A.

Step 1 Homogeneous: When employing homogeneous correction terms, the following result has been obtained for a constant matrix A and C in \([77]\) and \([49]\) Lemma 1 (see also \([145]\) in the case in which \(\tau = -1\)).

Lemma 5.3. Consider A and C defined in (69) and assume A and C are constant and of the form (57). Then, there exist real numbers \((c_1, \ldots, c_d)\) in \(\mathbb{R}^d\), such that the origin of

\[
\dot{e} = Ae - k_{\text{Hom}}(Ce), \quad e \in \mathbb{R}^d;
\]

is globally asymptotically stable.

The system (88) being homogeneous and its origin being asymptotically stable, when \(\tau < 0\), trajectories are converging to the origin in finite time.

Step 2 Homogeneous: Employing the robustness property of homogeneous systems, the following result has been obtained in \([49]\).

Proposition 5.4. Assume that the system (1) admit a continuous triangular normal form as in (61) with constant vectors A and C of the form (57) and with the mappings \(\varphi\) which satisfy for all \(i \in \{1, \ldots, d_\ell\}\), for all \((y, z_{a}, z_{b})\) in \(\mathbb{R} \times \mathbb{R}^{d} \times \mathbb{R}^{d}\) and \(t > 0\),

\[
|\varphi(y, z_{a}, \ldots, z_{a}, t) - \varphi(y, z_{b}, \ldots, z_{b}, t)| \leq b \sum_{j=2}^{(d_\ell - i - 1)} |z_{ja} - z_{jb}|^{\alpha_{ij}},
\]

with

\[
\frac{1 + (d_\ell - i - 1)}{1 + (d_\ell - j)} < \alpha_{ij} \leq 1, \quad j \leq i \leq d_\ell.
\]

Then, there exists \(\tau < 0\) and \(\ell > 0\) such that for all \(\ell > \ell^*\), the system \([65]\), \([66]\), \([85]\) is a robust finite-time observer with

\[
k(\hat{z}, y, t) = D_\ell k_{\text{Hom}}(y - C\hat{z})
\]

and \(D_\ell\) defined as in (72).

Note that no restriction is imposed on \(\varphi_{d_\ell}\) besides boundedness. In the limit case we take \(\tau = -1\) and we recognize the well-known robustness property of the sliding mode observer.

Note also that the use of more involved correction terms may give uniform finite time converging observer (see \([21]\), \([51]\)).

5.3.2. Homogeneity to allow non-globally Lipschitz normal form

Another result which has been obtained is to consider the case in which the normal form is locally Lipschitz but not globally Lipschitz. Employing homogeneous in the bi-limit correction terms (see \([17]\)) in combination with dynamics high-gain scaling, the following result have been obtained in \([18]\). Note that in that case the observer provides a converging estimation only for bounded trajectories.

Proposition 5.5. Assume that for all \(x(0)\) in \(X_0\) the solution \(x(t)\) is bounded for all positive time. Assume that the system (1) admit a triangular normal form as in (61) with C constant and when the matrix function A and the mappings \(\varphi_i\) which satisfy for all \((z, y, t)\) in \(\mathbb{R}^d \times \mathbb{R} \times \mathbb{R}\) and for all \(i \in \{1, \ldots, d\}\)

\[
0 < a_i(y, t) < \bar{a},
\]

\[
|\varphi_i(y, z_{ja} - z_{ja}, t) - \varphi_i(y, z_{ja}, \ldots, z_{ja}, t)| \leq \bar{b} \sum_{j=2}^{d} |z_{ja} - z_{ja}|^{\alpha_{ij}},
\]

with

\[
\bar{b} \sum_{j=2}^{d} |z_{ja} - z_{ja}|^{\alpha_{ij}} \leq \bar{b} \sum_{j=2}^{d} |z_{ja} - z_{ja}|^{\alpha_{ij}}.
\]

for some locally Lipschitz function \(\Gamma\). Then there exists a correction term \(k_{\text{Hom}}\) and three positive real numbers \((c_1, c_2, c_3)\) such that for all \(\ell > \ell^*\), the system \([65]\), \([66]\) is an asymptotic observer with

\[
k(\hat{z}, y, t) = D_\ell k_{\text{Hom}}(y - C\hat{z})
\]

and \(D_\ell\) defined as in (72).

5.4. Pure differentiators

In many works, researchers focused on the problem of estimating the derivatives (up to a certain order) of a time-varying output \(y\). Such a problem can be recast as the problem of state-observation for dynamical systems (1) that can be put into the form (85), \([145]\) in the case in which \(\hat{y}\) is bounded for all positive time. Assume that the system (88) being homogeneous and its origin being asymptotically stable, then trajectories are converging to the origin in finite time.

As shown in \([18]\), this observer is robust.
5.5. Use of interconnection

An interesting development in the context of observer design for systems in triangular normal form (see Definition 5.2) is the use of interconnection and cascades of low-order differentiators. The main motivations may be summarized as follows:

- to improve the performances of high-gain observers (e.g., in terms of peaking phenomenon and sensitivity to measurement noise);
- to improve the limitations of homogeneous approaches when the homogeneity conditions (89) or (92) are not satisfied.

Concerning the performances of high-gain observers, recall that when the measured output $y$ is affected by some measurement noise, namely $y = H(z,t) + v_y$ in place of (58), the bound (77) is then modified into

$$
|z(t) - \hat{z}(t)| \leq c_1 \ell^{d-1} \exp(-\ell c_2) |z(0) - \hat{z}(0)| + c_3 \ell^{d-1} \sup_{s \in [0,t]} |v_y(s)|
$$

for all $t \geq 0$ and for some $c_3 > 0$ independent of $\ell$. The inequality (78) highlights, as previously discussed, the peaking phenomenon and the important effect of the measurement noise $v_y$ on the asymptotic estimation. Furthermore, it can be proved that for high-frequency measurement noise the asymptotic gain behaves actually as $\ell^d$, see [29]. Such considerations motivate for the use of more sophisticated designs, based on the use of an interconnection of lower-dimensional observers so that to increase the relative degree between the measurement noise $v_y$ and the estimates $\hat{z}$, and at the same time, to relax the homogeneity conditions (89) or (92) in the context of homogeneous theory. Different techniques that can be also employed in the context of performances improvements are also discussed in Section 7.3.

The main idea of a cascade structure for triangular normal forms consists in employing a cascade of $d_c - 1$ lower-dimensional differentiators of order 2, each of them feeding the successive differentiator. The observer takes the form

$$
\begin{align*}
\hat{z}_{i\ell} &= F_i(y,t,\hat{z}_{12},\hat{z}_{23},\ldots,\hat{z}_{i(i+1)}) - k_{i1}(\hat{z}_{i\ell} - z_{i\ell}) \\
\hat{z}_{i(i+1)} &= F_{i+1}(y,t,\hat{z}_{12},\hat{z}_{23},\ldots,\hat{z}_{i(i+1)}) - k_{i2}\hat{z}_{i\ell} - \hat{z}_{i(i-1)}
\end{align*}
$$

with the conventions $\hat{z}_{01} = y$ and $\hat{z}_{d_c(d_c+1)} = 0$, and where the $k_i$’s are positive real numbers that will be selected later on. The overall state dimension of the observer is $2d_c - 2$. The indexes of the observer variables are selected with the convention that $\hat{z}_{i\ell}$ is the first state-component of the $i$-th block providing an estimate of the variable $z_{i\ell}$, and $\hat{z}_{i(i+1)}$ is the second state-component of the $i$-th block providing an estimate of the variable $z_{i(i+1)}$. As a consequence, for each variable $z_i$, with $i = 2,\ldots,d_c - 1$, we have two different estimates.

Depending on the design employed for the functions $k_{i1}, k_{i2}$, we obtain two different classes of observers.

**Linear gains**: By selecting the gains $k_{i,j}$ in (99) linearly

$$
k_{i,j}(s) = c_{i,j}s, \quad \forall i = 1,\ldots,d_c - 1, \ j = 1,2,
$$

we obtain the so-called low-power high-gain observer which provides an extension of Proposition 5.1 see, e.g., [232] [28] with the following result.

**Proposition 5.6.** Assume that the system (1) admits a triangular normal form (see Definition 5.2) with the mappings $F$ and $H$ which satisfy for all $(z,y,t)$ in $\mathbb{R}^d \times \mathbb{R}^d \times \mathbb{R}$

$$
\begin{align*}
\bar{a} &\leq \frac{\partial F_i(z,y,t)}{\partial z_i} < \bar{a}, \ i = 1,\ldots,d_c - 1, \ \bar{b}_c < \frac{\partial F_i(z,y,t)}{\partial z_i} < \bar{b}_c
\end{align*}
$$

for some positive real numbers $(\bar{a},\bar{a}_c,\bar{b},\bar{b}_c)$. Then, there exist positive real numbers $c_{i,j}, i = 1,\ldots,d_c - 1, \ j = 1,2$, and $\ell^* \geq 1$ such that, for all $\ell > \ell^*$, the system (99), (100) is a robust tunable asymptotic observer with $\ell_i = \ell$ for all

$$
i = 1,\ldots,d_c - 1.
$$

In particular, the observer (99) is able to recover the same type of ISS bound as the one given in (98). However, since the relative degree between the output $y$ and the estimate $\hat{z}$ is larger than one (in particular, when $y$ in $\varphi_i$ is substituted with $\hat{z}_{i1}$), the sensitivity with respect to high-frequency measurement noise is improved, see, e.g., [30]. Furthermore, by adding some saturation functions between the interconnections of each block, the peaking phenomenon can be removed when the state $z$ of the plant evolves in a known compact set, see [30].

Different versions of the low-power high-gain observer for systems in the prime form (56), (57) are the one proposed in [223] in which each block is implemented as a reduced-order high-gain observer (thus recovering an observer of total dimension $d_c - 1$), and the cascade high-gain observer proposed in [131], in which all but the first block are reduced-order observers (thus obtaining an observer of total dimension $d_c$).

**Nonlinear gains**: As proposed in [12] the gains $k_{i,j}$ in (99) can be designed following a mixed linear/homogeneous approach as

$$
\begin{align*}
k_{i1}(s) &= q(s), \\
k_{i2}(s) &= \text{sign}(s) + q(s), \quad q(s) = \text{sign}(ks)|s|^1 + s.
\end{align*}
$$

As explained at the beginning of the Section 5.3, the observer dynamics must be understood as a differential inclusion. The following result can be stated.

**Proposition 5.7.** Assume that the system (1) admits a continuous triangular normal form as in (61) with constant vectors $A$ and $C$ as in (57) and with the mappings
\( \varphi \) which satisfy for all \( i \) in \([1, \ldots, d \rceil\), for all \((y, z_{\rceil i}, z_{d-\rceil i})\) in \( \mathbb{R} \times \mathbb{R}^d \times \mathbb{R}^d \) and \( t > 0 \),

\[
|\varphi_i(y, z_{\rceil i}, \ldots, z_{d-\rceil i}, t) - \varphi_i(y, z_{\rceil i}, \ldots, z_{d-\rceil i}, t)| \leq \bar T_0 + \bar T_1 \sum_{j=2}^d |z_{\rceil j} - z_{d-\rceil j}|. \tag{104}
\]

Then, there exist positive real numbers \((k, \ell_1, \ldots, \ell_{d-1})\) such that the system \((99), (103)\), is a robust finite-time observer.

With respect to Proposition 5.4, we obtain much less restrictive conditions on the functions \( \varphi_i \). In particular, the homogeneous inequality \((89)\) is now replaced by \((104)\) in which each function \( \varphi_i \) is bounded by a linear and a constant term. To the best of the authors’ knowledge, a convergent observer of the form \((65)\) under the condition \((104)\) cannot be obtained, thus motivating the interconnection structure \((99)\) to be crucial for systems with such type of nonlinearities.

Note that an early version of the observer \((99)\) in the pure differentiator context (see Section 5.4) can be found in \((98)\), where the gains \( k_{i,j} \) in \((99)\) are selected following the homogeneous conditions with degree \( r = -1 \), namely as in \((87)\). Therein, however, the interconnection term \( \bar z_{i+j}(y_{i+j}) \) in the \( \bar z_{i+j}(y_{i+j}) \) dynamics is not employed and each block is actually implemented as a pure sliding-mode differentiator of order 2. Another possibility is finally to select the gains \( k_{i,j} \) in \((99)\) following standard homogeneous theory, see \((171)\). In this case, the homogeneous version of the low-power high-gain observer \((98)\) is recovered and a result similar to Proposition 5.4 can be established.

Finally, note that if the system \((1)\) has (uniformly) bounded trajectories and admits a continuous triangular normal form as in \((63)\) with constant vectors \( A \) and \( C \) as in \((57)\) and without any further assumption of regularity on \( \varphi \), it is proposed in \((49)\) to build a finite-time observer by interconnecting \( n \) homogeneous observers of degree \( r = -1 \) (see Section 5.3.1), with the \( i \)-th block of dimension \( i \) estimating \((x_1, \ldots, x_i)\). Indeed, thanks to triangularity, the estimate of \((x_1, \ldots, x_i)\) provided by the \( i \)-th block, which converges in finite-time, can be used to feed \((\varphi_1, \ldots, \varphi_i)\) in the \((i+1)\)th block and the homogeneous correction terms with \( r = -1 \) allow to handle the bounded nonlinearity \( \varphi_{i+1} \) on the last line. This observer is also shown to be uniformly asymptotically stable and robust.

6. Observers from distinguishability

When D. Luenberger published his first results concerning the design of observers for linear systems in \((154)\), his idea was to look for a (reversible) change of coordinates transforming the plant dynamics

\[
\dot{x} = Ax, \quad y =Cx,
\]

into a form

\[
\dot{z} = \Lambda z + \Gamma y
\]

with a Hurwitz, for which a trivial observer is simply made of a copy of the dynamics

\[
\dot{\hat{z}} = \Lambda \hat{z} + \Gamma y.
\]

Indeed, the estimation error \( e = \hat{z} - z \) then evolves simply along the contracting dynamics \( \dot{e} = \Lambda e \) and \( \hat{z} \) is obtained from \( \hat{z} \) by inverting the transformation. He proved that when the pair \((A, C)\) is observable, this is always possible via a linear stationary transformation \( z = T x \) with \( d_z = d_x \), for \( A \) any Hurwitz matrix in \( \mathbb{R}^{d_z \times d_x} \) with no common eigenvalues with \( A \), and \( \Gamma \) any vector in \( \mathbb{R}^{d_z \times d_x} \) such that the pair \((A, \Gamma)\) is controllable. This is based on the fact that the Sylvester equation

\[
TA = \Lambda T + \Gamma C \tag{105}
\]

admits in this case a solution that is unique and invertible.

Some researchers have therefore tried to reproduce Luenberger’s original methodology on nonlinear systems, i.e. find a (uniformly injective) transformation into a Hurwitz form

\[
\dot{z} = \Lambda z + \Gamma(y, t), \quad y = H(z, t) \tag{106}
\]

with a Hurwitz, and associated observer

\[
\dot{\hat{z}} = \Lambda \hat{z} + \Gamma(y, t) \tag{107}
\]

Unlike in Section 4 this procedure is not a linearization of the plant dynamics, since the output function \( H \) in \((106)\) can be any nonlinear function (see \((128), \text{Remark 4})\). This crucial difference leads to far less restrictive conditions on the system, and because the corresponding observer \((107)\) is a simple copy of the dynamics, it is not even necessary to have an explicit expression for \( H \).

6.1. Autonomous systems

The case of autonomous nonlinear systems was first proposed and analyzed in a general context by \((213)\). It was rediscovered later by \((128)\) who gave a local analysis close to an equilibrium point under conditions relaxed later on in \((140)\). The localness as well as most of the restrictive assumptions were then by-passed in \((116)\) leading to the so-called KKL-observers or nonlinear Luenberger observers, which is also strongly related to the observer proposed in \((133)\). More precisely, in \((16)\), the authors investigate the possibility of transforming an autonomous system \((3)\) into a Hurwitz autonomous form \((105)\), with \( \Gamma(y, t) = \Gamma(y) \). This raises the question of finding, for some integer \( d_z \), a \( C^1 \) function \( T : \mathbb{R}^{d_z} \to \mathbb{R}^d \) verifying

\[
\frac{dT}{dx}(x)f(x) = \Lambda T(x) + \Gamma(b(x)) \quad \forall x \in X \tag{108}
\]

with \( \Lambda \) some Hurwitz matrix of dimension \( d_z \) and \( \Gamma : \mathbb{R}^{d_z} \to \mathbb{R}^{d_z} \) some continuous function. The existence of such a transformation is shown for any Hurwitz matrix \( \Lambda \) and for some well-chosen functions \( \Gamma \) under the only assumption that the system is backward-complete in \( X \) (\((116, \text{Theorem 2})\)). Of course, this is

\( \text{Any solution exiting } X \text{ in finite backward time must cross the boundary of } X. \text{ See } (116, \text{Definition 1}) \).
not enough since, as we saw in Theorem 2.1, it is required that $T$ be uniformly injective on $X$ to deduce from the estimate $\tilde{z}$ of $T(x)$ an estimate of $x$. It is shown in [16, Theorem 3] that injectivity of $T$ is achieved for almost any diagonal complex Hurwitz matrix $\Lambda$ of dimension $[d_1 + 1)d_1$ and for any $\Gamma$ verifying some growth condition, under a backward-distinguishability assumption.

**Definition 6.1.** Given a set $O \supset X$, the system (2) is backward $O$-distinguishable on $X$ if for any $(x_{a0}, x_{b0}) \in X^2$ such that $x_{a0} \neq x_{b0}$, and for any solution $(x_{a}, x_{b})$ to (2) initialized at $(x_{a0}, x_{b0})$, there exists $t < 0$ such that both $x_{a}$ and $x_{b}$ are defined in $O$ on $[t, 0]$ and

$$h(x_{a}(t)) \neq h(x_{b}(t)).$$

In other words, two different states in $X$ can be distinguished in $O$ from the past values of the output. In the case where $X$ is bounded, the result of [16] can be simplified as follows.

**Theorem 6.1.** Assume that $X$ is bounded and there exists an open bounded subset $O$ of $\mathbb{R}^{d_1}$ containing $c(X)$ such that the system (2) is backward $O$-distinguishable on $X$. Then, there exists a strictly positive number $\ell$ and a set $R$ of zero Lebesgue measure in $\mathbb{C}^{d_1+1}$ such that denoting

$$\Omega = \{ \lambda \in \mathbb{C} : R(\lambda) < -\ell \},$$

for any $(\lambda_1, \ldots, \lambda_{d_1+1})$ in $\Omega^{d_1+1} \setminus R$, there exists a $C^1$ map $T : O \rightarrow \mathbb{R}^{[d_1+1)d_1}$ uniformly injective on $X$ and verifying (108) with

$$\Lambda = \tilde{\Lambda} \otimes I_{d_1}, \quad \Gamma(y) = (\tilde{\Gamma} \otimes I_{d_1}) y,$$

and

$$\tilde{\Lambda} = \begin{pmatrix} \lambda_1 & & \\ & \ddots & \\ & & \lambda_{d_1+1} \end{pmatrix}, \quad \tilde{\Gamma} = \begin{pmatrix} 1 \\ \vdots \\ 1 \end{pmatrix}.$$  (109)

It is therefore possible to design an observer for an autonomous nonlinear system (2) under the weak assumption of backward-distinguishability. Note that with a stronger assumption of strong differential observability of order $m$ (see Definition 5.1), and still in a bounded set, it is also proved in [16, Theorem 4] that the injectivity of $T$ is ensured for any choice of $m$ real strictly negative $\lambda_i$ smaller that $-\ell$ with $\ell$ sufficiently large.

Note also that assuming differential observability, it is shown in [11] that the observer is exponential in the sense of (7). Moreover, it can be shown that the observer obtained is robust since it satisfies an asymptotic gain property as in equation (10).

6.2. Time-varying controlled systems

After first steps in [109, 227] for linear time-varying systems, an extension of the Luenberger design to nonlinear controlled systems was considered in [84], following the ideas of [135]. In [84], injectivity of a time-varying transformation $T$ is proved only under a so-called "finite-complexity" assumption, originally introduced in [135] for autonomous systems. Unfortunately, this property is very restrictive and hard to check. Besides, no indication about the needed dimension $d_1$ is given. Those problems were then overcome more recently in [45] with results of existence and injectivity of a time-varying transformation under more standard and constructive observability assumptions.

More precisely, consider $d_1 \in \mathbb{N}$, a Hurwitz matrix $\Lambda \in \mathbb{R}^{[d_1+1)d_1}$, and a vector $\Gamma \in \mathbb{R}^{[d_1+1)d_1}$. In order to transform a general time-varying system (1) into the Hurwitz form (106) with $\Gamma(y, t) = \Gamma y$, we need to find a transformation $T : \mathbb{R}^{d_1} \times [0, +\infty) \rightarrow \mathbb{R}^{d_1}$ such that for any $x$ in $X$ and any time $t \in [0, +\infty),$

$$\frac{\partial T}{\partial x}(x, t)f(x, t) + \frac{\partial T}{\partial t}(x, t) = \Lambda T(x, t) + \Gamma h(x, t).$$  (110)

According to Theorem 2.1 (107), then gives an observer for (1) if besides $T$ becomes injective uniformly in time and in space at least after a certain time.

It is shown in [45, Lemma 1] that a solution to (110) always exists if solutions to (1) initialized in $X$ do not explode in finite backward time. Note that this latter assumption can always be made to hold if $X$ is bounded by saturating $f$ outside of $X$. Then, still under a backward-distinguishability condition, but this time in finite time, "generic" injectivity is proved in [45, Theorem 3].

**Theorem 6.2 ([45]).** Assume that $X$ is bounded and the system (1) is backward-distinguishable in time $t_d$ on $X$, i.e. for any $t_0 \geq t_d$ and any pair of solutions $(x_a, x_b)$ to (1) verifying $(x_a(t_0), x_b(t_0)) \in X^2$ with $x_a(t_0) \neq x_b(t_0)$, there exists $s \in [t_0 - t_d, t_0]$ such that

$$h(x_a(s), s) \neq h(x_b(s), s).$$

Then there exists a set $R$ of zero Lebesgue measure in $\mathbb{C}^{d_1+1}$ such that for any $(\lambda_1, \ldots, \lambda_{d_1+1})$ in $\Omega^{d_1+1} \cap R$ with $\Omega = \{ \lambda \in \mathbb{C} : R(\lambda) < \ell \},$ there exists a $C^1$ map $T : X \rightarrow \mathbb{R}^{[d_1+1)d_1}$ verifying (110) with

$$\Lambda = \tilde{\Lambda} \otimes I_{d_1}, \quad \Gamma = \tilde{\Gamma} \otimes I_{d_1},$$

and $\tilde{\Lambda}, \tilde{\Gamma}$ defined in (109), such that $T(\cdot, t)$ is injective on $X$ for $t > t_d$.

Note that the assumption of backward-distinguishability in finite time is in particular verified when the system is instantaneously backward-distinguishable, and a fortiori when the map made of the output and its Lie derivatives up to a certain order is injective with respect to $x$ (weak differential observability). Actually, under a strong differential observability assumption on (1), it is shown in [45, Theorem 2] that, with sufficiently fast eigenvalues, $d_1$ can be chosen according to the order of differential observability of each output.

---

7Separating the real/imaginary parts, the observer is thus of dimension $2(d_1 + 1)d_1$ on $\mathbb{R}$.

8We could have considered the more general Hurwitz form (106), but taking $\Gamma$ linear and stationary is sufficient to obtain satisfactory results.
6.3. Computation of $T$

All in all, the main difficulty of the KKL observers lies in the computation of the map $T$, let alone its left-inverse $T^{-1}$. From a theoretical point of view, an injective solution $T : O \rightarrow \mathbb{R}^{d \times r}$ to (108) shown to exist in Theorem 6.1 is written explicitly as

$$T(x) = \int_{-\infty}^{0} e^{-\lambda T} h(h(x, \tau)) \, d\tau,$$

(111)

where $\hat{x}(x, \tau)$ is the solution at time $\tau$ and initialized at $x$ to modified dynamics $\dot{x} = \tilde{f}(x)$ with $f = \tilde{f}$ on $X$. A similar expression exists for the time-varying context (see [45, Lemma 1]) Unfortunately, the use of those explicit expression (111) is not easy since it necessitates to integrate backwards a differential equation at each time step. Several examples in [44, Section 6.3] show how the map $T$ can sometimes be computed without relying on the integral formulas. Otherwise, an approximation strategy was proposed in [160] in the context of output regulation, and a learning-based strategy was presented in [78] in order to learn offline the map $T$ via neural networks.

Note that when the time dependence of (11) comes from an input $u$, namely we have (3), then the map $T(x, t)$ depends implicitly on the whole past trajectory of $u$ and is thus not computable offline. An alternative would be to keep the stationary transformation obtained for some constant value of $u$ (for instance the drift system at $u \equiv 0$) and prove that the additional terms due to the presence of $u$ do not prevent convergence. In the context of input-affine systems [50], this can be done under very strong assumptions of uniform observability and strong differential observability of order $d_z$ of $f$, namely in the same context as [100] allowing to transform the dynamics in the triangular form (59) (see [45, Theorem 4]).

7. About the implementation of an observer

7.1. Computation of $T$ : the left-inversion problem

The previous sections have shown that it is possible, under certain conditions, to build an observer by transforming the plant dynamics into a favorable form for which an observer is known. It follows that the dynamics of the plant and of the observer are not expressed in the same coordinates and often evolve in spaces of different dimensions. In order to obtain an estimate for the system state, i.e. compute $T$ (or even sometimes to write the observer dynamics), it is necessary to invert the injective transformation $T$. But even if $T$ is stationary, this inversion is difficult in practice, when an analytical expression for a global inverse is not available. Indeed, the inversion then usually relies on the resolution of a minimization problem of the type

$$\hat{x} = \min_{x \in X} |T(x) - \tilde{x}|$$

with a heavy computational cost and the risk of local minima.

In the case where $T$ is a diffeomorphism on an open set $O$ containing $X$, one may hope to avoid this minimization by implementing the observer (4) directly in the $x$-coordinates with

$$\hat{x} = \left( \frac{dT}{dx}(\tilde{x}) \right)^{-1} T'(T(\hat{x}), y, t).$$

(112)

This is done for instance in [235, 101, 74, 170, 155, 50, 81, 32]. But even in this apparently simple case, the observer (112) must be treated carefully. Indeed, although $x$ remains in $O$ where the Jacobian of $T$ is invertible, there is no guarantee that $\hat{x}$ will, in particular during transients behaviors where the solutions $t \mapsto \tilde{x}(t)$ of (4) may leave the image set $T(O)$. For instance it is shown in [50] that the observer proposed in [101] admits solutions that explode in finite-time. This can be solved either by modifying the observer dynamics $F$ to constrain the state in $T(O)$ as in [155, 31, 32], but some convexity properties are needed to guarantee convergence is preserved ; or by keeping the observer dynamics $F$ unchanged but modifying $T$ outside of $X$ so that $T(O) = \mathbb{R}^m$, as proposed in [50]. But there is no systematic method to perform this image extension in practice.

Now, when $d_z > d_x$, i.e. the Jacobian is rectangular and $T$ is at best an injective immersion, (112) cannot be implemented. It was proposed in [50] to extend $T$ into a surjective diffeomorphism $T_e$, by adding $d_z - d_x$ fictitious states $w$ to $x$, such that

$$T_e(x, 0) = T(x) \quad \forall x \in X$$

and implement

$$\begin{align*}
\dot{\hat{x}} &= \begin{pmatrix} dT_e & d(x, w) \end{pmatrix} (\tilde{x}, \tilde{w}) \left( T_e'(\tilde{x}, \tilde{w}), y, t \right) \\
\dot{\tilde{w}} &= \begin{pmatrix} f(T_e(\tilde{x}, \tilde{w})) \end{pmatrix}^{-1} \left( T_e'(\tilde{x}, \tilde{w}), y, t \right).
\end{align*}$$

Another path is to implement Newton-like or gradient-like algorithms in parallel to (4), namely add dynamics of the type

$$\dot{x} = K(\hat{x})(\hat{x} - T(\hat{x}))$$

where $K(x) = \frac{dT}{dx}(x)^T$ or $K(x) = \left( \frac{dT}{dx}(x)^T \frac{dT}{dx}(x) \right)^{-1} \frac{dT}{dx}(x)^T$ as proposed in [166, 34] for high gain observers. But the convergence of the obtained observer is only local. Similarly, continuation algorithms which “follow” the minimum of $\|T(x) - \tilde{x}\|^2$ can be used under a convexity assumption like in [109], but again the convergence is only local.

Finally, one may mention an alternative route followed in [46], which consists in implementing in parallel to (112) an independent practical observer which is used to reset $\hat{x}$ whenever it gets too close to the boundary of $O$. Here, only a finite-number a approximate left-inversions of $T$ need to be carried out and the convergence is global.

7.2. Taking into account state constraints

In many applications, the state of the plant is known to evolve in a given set or manifold $X$, describing the set of interest of the variables for the considered set of initial conditions $X_0$. Examples include positive systems [91], quaternion or other Lie groups ( [205, 162, 108, 60]), general manifolds admitting symmetries ( [2]). When the observer is implemented in other coordinates $z = T(x)$, also $z$ is thus known to remain in the manifold $Z = T(X)$. But unless the observer is designed in a way that incorporates these constraints, $\hat{x}$ (resp. $\tilde{z}$) could in principle leave the set $X$ (resp. $Z$) for some time, because of transient dynamics or disturbances. A typical example is the peaking phenomenon occurring in high-gain observers [130]. During
these excursions outside of $\mathcal{X}$ (resp. $\mathcal{Z}$), the estimate is known to be inaccurate and cannot be exploited. Worse, the observer maps $\mathcal{F}$ and $\mathcal{T}$ may not be defined or this may lead to instability in the context of output-feedback. Besides, it is advantageous from a numerical implementation point of view to specify beforehand the range of each variable and to have this range as small as possible to increase precision. This is not possible if the estimates are not guaranteed to remain in (or close to) $\mathcal{X}$ (resp. $\mathcal{Z}$).

A simple idea to address some of these issues is to saturate or to project $\hat{x}$ into $\mathcal{X}$, while preserving the observer’s inner dynamics $\mathcal{F}$, namely change only $\mathcal{T}$. However, the inner observer state $\hat{z}$ can still venture far from its “nominal” set $\mathcal{Z}$. A natural way to overcome these issues is to constrain $\hat{z}$ in a given set $\mathcal{Z} \supset \mathcal{Z}$. This has nevertheless to be done with care to preserve the observer convergence and performance. In control problems, combining convergence with invariance constraints is typically handled through control barrier functions [10], leading to the so-called safety control. However, those methods do not transpose easily to the estimation field because the state, and thus the value of the Lyapunov function, are unknown. Instead, two different strategies may be followed:

- either the observer dynamics $\mathcal{F}$ are designed from the start to ensure simultaneously convergence of the estimation error and invariance of $\mathcal{Z}$;
- or the observer dynamics $\mathcal{F}$ are first designed along general unconstrained methods, and then modified in a second step to ensure the estimate remains in a particular set $\mathcal{Z}$.

Along the first path, we may mention invariant observers [2] in which the observer dynamics are designed so that to respect some state space symmetries. Similar ideas have been developed in the filtering context in [162, 60] or in [108] for state estimation for rotation matrices and more generally for Lie groups [143, 177, 40, 157, 156]. This is also the path which is followed in [39, 61] for positive systems in which the positive orthant is made invariant along the observer dynamics.

On the other hand, along the second path, projection-based solutions have been proposed for high-gain observers in [155] for Lur’e type systems in [221], for Kalman filters [216, 43], within the framework of projected dynamical systems in [113] for exponentially convergent observers with linear correction terms, and in [27] for any type of observer with quadratic Lyapunov functions under general nonlinear convex constraints. Actually, instead of projecting $\hat{z}$ or $\mathcal{F}$, [27] also proposes to consider the constraint information as an additional pseudo-measurement and add a correction term in $\mathcal{F}$ in a way that does not increase the derivative of the Lyapunov function (to preserve convergence) but that ensure $\hat{z}$ remains in $\mathcal{Z}$.

### 7.3. Tuning and characterization of performances

#### 7.3.1. Analysis of the behaviour of observers

From the practical point of view, it is in general important not only to guarantee that an observer is asymptotic, but also that its performances are satisfactory in terms of transient response (convergent speed) and steady-state behaviour in presence of measurement noise and possibly model uncertainties [35]. For linear systems, a certain number of different linear tools are available for both synthesis and design, such as Laplace and Fourier transform, $H_{\infty}$ or $L_2$ gain designs (based on the minimization on an input-output gain and the bounded real lemma) or Kalman filtering stochastic approach, see, e.g., [125], just to cite a few. However, it is also very well known that certain limitations cannot be overcome with standard linear tools, see, e.g., [208].

For nonlinear observers, one may gain in flexibility in using nonlinear/hybrid tools, but it has to be stressed that it is also much harder, in general, to analyze the desired aforementioned performances characteristics. As a matter of fact, the tool which is typically employed is the one of Lyapunov functions, allowing both synthesis and design, with the performances that are characterized in terms of classical ISS bounds, see, e.g., [273]. For the majority of the observer design techniques presented in these survey, such a Lyapunov analysis can be easily developed and it is not hard to verify that most of observers are indeed robust according to the definition given in the introduction, see inequality [10]. However, it is also important to remind that such bounds are in general conservative, because Lyapunov analysis reflects the (worst-case) asymptotic gain of the estimation error [10], failing to capture any frequency information. In this sense, the analysis of the behaviour in presence of high-frequency measurement noise developed in the context of high-gain observers [29, 30] is a remarkable attempt in such a direction. On the other hand, Lyapunov analysis may also be used as a design tool to improve certain properties, as shown in [22], where a hybrid scheme is employed to reduce the peaking phenomenon of high-gain observers.

#### 7.3.2. Use of variable gains and multi-observers

A typical limitation in observer design is the requirement of having fast convergence and a small influence of the measurement noise in steady-state. Intuitively, a “large-gain” (in terms of magnitude) is needed to achieve fast convergence, but a “small-gain” is desired to minimize the effect of the measurement noise on the observer-dynamics. Variable gains can therefore be employed to improve performance either in terms of sensitivity to measurement noise, or in increasing the speed of convergence of the observer. This can be achieved with continuous-time gain adaptation, for instance, by means of Riccati or Lyapunov based designs such as in Kalman filters [125]. Kalman-like observers, see, e.g., [58, 71], and in high-gain observers [206], or employing switching strategies between different gains in a hybrid/switching context, see, e.g., [5, 75, 81].

In the same spirit of employing different gains, another methodology consists in using a bank of observers and to estimate online the “best-one”, i.e. the one providing the more accurate estimate. Such an approach has been investigated, for instance, in [138, 181, 73, 87, 35].

Finally, we recall also [85, 169, 149, 198] where different observers with different gains are combined to obtain finite-time estimation.
7.3.3. Use of filters

A different route that it is often used in observer design to improve the performance in presence of measurement noise is based on the use of filters in order to reduce its effect. Although filtering the sole measured output may introduce phase-lag in the estimates, the use of filters for the output-error estimation error may improve the sensitivity properties of the observer while preserving its asymptotic convergence in nominal “noise-free” conditions (see [33]). A well-known example of such an approach is the so-called Proportional-Integral Observer (PI-observer) in which both the output estimation error and its integral are typically employed in the observer design, enlightening remarkable improvements, see, e.g., [42], [73], [67]. The so-called “low-power high-gain observer” approach investigated in [28], [30] founds on the same principle of augmenting the relative-degree between the measurement noise and the state estimate, in order to increase the filtering properties at high-frequencies. In this case, the filters are directly inherited from the cascade structure, see Section 5.5. The use of more general low-pass filters have also been investigated in the context of high-gain observers (see, e.g., [22], [33]) and homogeneous observers (see, e.g., [122]) presented in Sections 5.2 and 5.3.

Based on similar ideas, we recall also the recent idea in which the observer is designed by using integrals of the output combined with a moving-horizon strategy, see [167], [168].

Finally, recent developments showed how the use of saturation (also denoted as Stubborn observer) or dead-zone with adapting thresholds may be employed to improve the sensitivity with respect to sporadic impulsive noise and biased noise, see, e.g., [8], [76], [26].

7.4. Output sampling and continuous-discrete observers

In practice, the output $y$ is sampled and only available intermittently at specific time instances. A first natural idea is to approximately discretize the continuous-time observer designed for the continuous-time plant model, or to design a discrete-time observer for an approximate discretized model of the plant. This typically leads to practical observers, and attention must be payed to the discretization method in order not to destroy the convergence properties of the observers, see, e.g., [24].

When the sampling time is not sufficiently small for such discretizations, or when asymptotic convergence is sought, specific continuous-discrete observers need to be designed, considering the time elapsed between successive sampling events. Generally, they consist either of a continuous-time predictor made of the copy of the plant dynamics with discrete updates of the estimate at each sampling time, or of a continuous-time observer with a sample-and-hold innovation term.

In this second case, convergence of such observers was first shown under the assumption that the sampling period is sufficiently small (this strategy is also known in literature as emulation approach), for linear observers in [220], high-gain observers in [79], [92], and contractive observers in [159]. Using the hybrid formalism proposed in [104], general conditions in the context of network communications have been proposed in [179] and [180] for robust nonlinear observers and reduced-order observers. More sophisticated designs have been developed for arbitrary constant sampling period [19], and more generally for sporadic measurements, using sample-and-hold strategies [12], [36] or discrete updates of the estimate at the sampling times [163], [85], [89], [209], [52], [148], [4], among others.

Actually, when we know that the time elapsed between two successive sampling events always belongs to a certain set, the observer can be modeled by an autonomous hybrid system [104]. Via this formalism, it is shown in [52] that the discrete updates of the estimate at the sampling time, should be designed as for a discrete observer of an equivalent discrete-time system, made of the plant dynamics sampled at the sampling times. For linear systems, this allows to use the gains of a discrete Kalman filter [52], or recover the matrix inequalities obtained for instance in [191], [95]. For Lipschitz nonlinear systems, such tools may still be used when the dynamics are in the convex hull of linear dynamics [80].

Last but not least, one should also mention the literature of event-triggered observers when the sampling times of the output can be triggered based on a policy defined by the observer or by a smart-sensor (i.e., a sensor equipped with computational capacities) that decides when to transmit the information. We briefly recall [211], [210], [88] concerning the use of event-triggering strategies and [15], [189] for self-triggering strategies. See also [179] and references therein.

7.5. Adaptive observers

It may happen that some parameters of the plant dynamics [1] are unknown or not precisely known. That is why a lot of researchers devoted their attention to the design of observers for systems of the form

$$x = f(x, t, \theta), \quad y = h(x),$$

where $\theta \in \mathbb{R}^d$ is a set of parameters characterizing the plant’s dynamics and which is unknown: we talk about adaptive observers. Within this context, two main approaches may be pursued.

Joint estimation: The first one consists in considering the constant parameters $\theta$ as an additional state with a pure integrator dynamics, i.e., $\dot{\theta} = 0$. In such a case, one can recast the observation problem for the extended state $(x, \Theta)$ and re-apply, for instance, one of the technique reviewed in this survey. In doing so, joint-observation requires the appropriate observability assumption to hold for the full state $(x, \Theta)$. See, for instance, [1] for the case of KKL observers.

Disjoint estimation: A second approach is to consider the estimation problem disjoint from the “identification” problem of the parameters and follow typical adaptive control techniques [119], [36], [142], [174]. In doing so, one is typically interested in the convergence of the state estimation error without any requirement/guarantee of the correct estimation of the parameter $\theta$. Such an approach has been extensively studied over the last decades with “ad-hoc” solutions based on the particular structure/properties of the
plant’s dynamics. See, for instance, in the following (non-exhaustive) list of references: [41, 68, 72, 153, 93, 161, 229, 238].

We remark that as discussed in [57], under some persistence of excitation assumptions, the two approaches may be interchangeable, namely when joint estimation can be employed, then a disjoint strategy can be pursued, and vice-versa.

7.6. Disturbance Observers and Extended State Observers

In some applications such as disturbance estimation and output feedback stabilization, it is commonly assumed that the system \( \dot{x} = f(x, u) \) is transformed into a system of dimension \( d_r \) of the form

\[
\dot{z} = Az + \varphi(t, z, \nu_c), \quad y = Cz
\]

with \((A, \varphi, C)\) being a triplet in prime form (see [57]), and \( \nu_c \) being an unknown input to be estimated. By considering \( \nu_c \) as a fictitious state (as often done in adaptive control, see Section 7.5), the dynamics of which is modelled as \( \dot{\nu}_c = 0 \), one can then design a differentiator (following the prescriptions of Section 5) of order \( d_r + 1 \) in order to have an approximate estimation of \( \nu_c \) and at the same time increase the performances of the observers in terms of asymptotic gain with respect to \( \nu_c \).

Such an approach is often denoted as Extended State Observer (shortly ESO), see, e.g., [107] and references therein, or extended high-gain observer, see, e.g., [172]. Design philosophy and convergence proofs follow the same principles presented in Sections 5.2 and 5.3. Concerning other classes of disturbance observers, we refer to the survey [190] and references therein.

7.7. Use of observers in feedback control

One of the main motivations for the use of an observer in practical problems is given by feedback control when only a part of the state can be measured. In practice, a common approach consists in designing first a state-feedback design, and then replace the state by its estimate provided by an observer.

In some applications such as disturbance estimation and output feedback stabilization (as hybrid, of large dimension, or with delayed measurements) is not covered by this survey. The use of observers for practical implementation for (possibly large-dimensional) systems can be difficult. For instance, KKL observers provide a very general answer to the observation problem, but the explicit construction of the transformation \( T \) remains problematic apart from particular applications [158, 48]. Also, the inversion of the map \( T \) in most of the designs still remains a numerical obstacle and leads practitioners to prefer observers written in the plant coordinates, such as the EKF, even at the price of local convergence. Moreover, the optimal selection of the observer’s parameters (in order to guarantee some desired performances) remains generically an open problem.

8. Conclusions

In this survey we have reviewed the main methods to design an asymptotic observer for finite dimensional nonlinear dynamical systems, that have been developed in the last six decades. They are summarized in Table 1. These methods have been classified based on the observability property available on the given dynamical system. Such an approach allows to obtain a general and unifying point of view on this topic. Although in its sixties, this research theme is still young and active. This is illustrated by the recent publications to which we have referred in the course of this paper. However, some difficulties remain unsolved and we do not yet have a complete solution to the observation problem in the nonlinear context. For example, it remains difficult to characterize the existence of observers for systems with inputs.

Also, even if the theory presented all along the paper may guarantee the existence of an observer, its construction and practical implementation for (possibly large-dimensional) systems can be difficult. For instance, KKL observers provide a very general answer to the observation problem, but the explicit construction of the transformation \( T \) remains problematic apart from particular applications [158, 48]. Also, the inversion of the map \( T \) in most of the designs still remains a numerical obstacle and leads practitioners to prefer observers written in the plant coordinates, such as the EKF, even at the price of local convergence. Moreover, the optimal selection of the observer’s parameters (in order to guarantee some desired performances) remains generically an open problem.

This explains why state observers for nonlinear systems are not systematically implemented in real-life applications. However, many examples show their relevance (see for instance [2]), see also the soft sensors industry) and we hope that this survey will participate in their dissemination. It is also important to highlight that in many practical applications, discrete-time observers, such as Extended Kalman Filters (and its modifications, such as Unscented EKF, Extended EFK or Ensemble EKF), moving horizon observers or particle filters, are directly designed and implemented. An exhaustive overview of discrete-time approaches is out of the scope of this article but of great interest for applications.

Some theoretical problems were not addressed during this study and may constitute future research themes. For instance, designing observers for more complex dynamical systems (such as hybrid, of large/infinite dimension, or with delayed measurements) is not covered by this survey. The use of observers for feedback control in the presence of observability singularities is also of great interest and a rich open research problem.

Finally, an approach that seems promising is the joint use of these methods in combination with techniques resulting from
data analysis and supervised learning methods. Along these lines, some preliminary results can be found in [159] [78].
